A great many people exhibit considerable hostility to sanitary measures. No doubt, in many cases, because they touch the pocket. But some I have met with say they are actuated by their love of liberty, and they hold that sanitarians are always restricting the liberty of the individual. It seems rather unreasonable of them, but they may now quote a philosopher in their support. Mr. Herbert Spencer in his new book "Facts and Comments," puts the sanitary class with the military and clerical classes and holds that the sanitarians have an interest to keep up, just as he thinks the army and navy exist for the benefit of officers and the church for that of the clergy. I am not sure it is merely sanitarians he objects to, I rather think he is prejudiced against the whole body medical. He is almost, if not quite, an anti-vaccinationist, and that on grounds which seem no more satisfactory from a philosophical point of view than from the aspect of "Facts" to which his "Comments" are altogether opposed. He assumes that "interference with the order of Nature has various sequences other than that counted upon," which is not worth while to dispute. Then he goes on to say that "the assumption that vaccination changes the constitution in relation to smallpox, and does not otherwise change it, is sheer folly." That may also be granted, but the philosopher should remember that such change as he declares must take place cannot be injurious, since millions who have been vaccinated have not only escaped smallpox but have enjoyed healthy lives afterwards. This is a "fact" on which he might well "comment." His confidence in his own knowledge of medical questions is as full as that of the man in the street and his assertions almost as authoritative. He talks of measles and influenza in a way to make epidemiologists laugh. He assumes they have become more serious in the last half century, and implies that this may be due to vaccination having produced a relative debility of constitution. The suggestion reminds me of a gentleman who labored hard to persuade people that the potato disease was produced by laying down railways.

The vacancy in the office of Registrar-General has once more been filled by the appointment of a politician instead of a scientific man. A relative of Lord Iddesleigh was given the post two years ago to the disgust of the profession. He is now made under-secretary for Scotland, for which possibly he may have some qualification. But the assistant under-secretary, who also might have been qualified for promotion, is brought to London to be Registrar-General. Is it not "very like a job"? The experience of an under-secretary is no qualification for such an office as the Registrar-General. It is true that he need not trouble himself, as the staff is thoroughly efficient. But then why should not the chief of the staff be promoted. If not let the office be abolished rather than remain a sinecure for political aspirants.

The King's Hospital Fund has received £10,000, being a coronation gift sent to His Majesty by Mr. R. Lucas Tooth of Australia.

Dr. Stiven of Harrow died on the 12th inst. of acute pneumonia. He took an active part in municipal matters in Harrow, where he was much appreciated for his good works, both public and private. He was only fifty-one years old.

Mr. J. E. Edwards, who died on the 9th inst., at Eastbourne, had reached the age of ninety.

Surgeon Lieut.-Col. McKenna, I.M.S. (retired), died in France on the 4th inst., aged sixty.

HOSPITALS AND CHRONIC CASES.

To the Editor of the Medical Record:

Sir: It is of very frequent occurrence that patients suffering from chronic or incurable diseases are refused admission to the various private hospitals in this city. The public at large not familiar with hospital work may condemn the action of the hospital authorities who are sometimes obliged to send patients back in the very conveyance in which they are brought to the institution, not aware that the hospital may be overcrowded, and that, perhaps, fifty or more urgent cases are on its waiting list; and that by admitting a patient suffering from chronic disease a great injustice would be done to those who could be benefited or cured in the hospital within a short time, while the chronic patient may occupy a bed for months, and keep away ten other patients within this period.

While a good many physicians in this city are thoroughly acquainted with these facts, and act accordingly, there are many, however, who ignore the existing conditions, and frequently send to hospitals patients in the last stages of phthisis, nephritis, diabetes, and other similar diseases. When a patient in such a condition arrives at the hospital he is, of course, examined, and if found in an extremely weak condition or, as often happens, pulseless, the institution is compelled to admit him without question. I am cognizant of instances in which physicians have boasted to friends of their patients that it was only through their influence that the patient was kept in the hospital.

If a physician feels thoroughly convinced that even a chronically sick person is a suitable hospital case, it is his duty to communicate with the hospital authorities before sending his patient to the institution. This would save physician, patient, and hospital officials unnecessary and unpleasant anxiety and trouble; general hospitals are primarily for the acutely ill; this is the keynote of my letter.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 7, 1902.

A Variety of Skin Lesions Treated By X-Ray.—Edith R. Meek reports a case of lupus vulgaris, another of hirsuties, and a third of excema, treated successfully by the use of the *x*-rays.

Electricity: Its Use in Gynecology.—W. H. White gives a brief historical sketch of the uses of electricity in gynecological practice, and enumerates the different forms of electrical apparatus employed at present. For the purpose of faradization he recommends the use of a high-tension coil like the Kidder coil, or a set of those called the "Engleman coils." The galvanic apparatus that he uses is an office cabinet connected with the street current and controlled by lamps, besides being fused. In addition to these two forms of apparatus, the sinusoidal and the static machine are considered useful. The principal disorders in which electricity in its various forms may be applied are amenorrhea, menorrhagia, metritis, ovarian inflammations, and salpingitis. In most cases of tumor surgical treatment is regarded as preferable to electrolysis.

Multiple Fibroids of the Uterus.—Samuel Breck describes a specimen of multiple fibroids obtained by autopsy from an unmarried negress. The largest of the tumors, the size of a small watermellon, had become cystic and had ruptured into the peritoneum in its upper and posterior portion. The opening was sealed by exudate at the time of the autopsy. The tumor and the abdomen were full of rather thin greenish pus, in quantity about half a pailful. The tumors and the peritoneum were covered with a recent fibrinous exudate. In addition to the main tumor, which was pedunculated and rose to the epigastrium, were numerous small ones, varying from the size of a cherry stone to that of an orange. They were subserous, the uturus being but little enlarged. The tubes and ovaries were healthy. As a rather rare complication there was complete prolapse of the vagina, with elongation of the supravaginal cervix. The prolapse had evidently been of long standing, as the original wall was much thickened and showed ulceration.

Journal of the American Medical Association, Aug. 9, 1902.

Results Obtained in the Treatment of Acne by Exposure to the X-Rays.—R. R. Campbell reports fifteen cases of acne treated with uniformly good results by the *x*-rays, a medium soft tube with weak light being used. None of the patients were subjected to either internal treatment or external applications while under exposure to the rays.

Plastic Surgery of the Female Urethra, with a Report of a Unique Case.—Henry P. Newman reports the case of a woman who, as the result of a difficult labor two years before, suffered an extensive tear of the bladder floor and complete obliteration of the urethral tract, which was laid open the entire length. When seen by the writer, she had a veritable exstrophy of the bladder, the walls of which were inflamed and thickened. No trace of the urethra could be made out. The small, hyperinvoluted uterus was deformed by tears and resulting scars, the cervix drawn forward and downward by the large cicatrix in the small vagina. Three attempts were made to reestablish the urethral canal by taking flaps from the vulva on either side and suturing them after splitting the bladder and vaginal wall. The results having been only partially successful, the author proposes, in another case presenting all the formidable features of this one, to operate in this wise: After the opening of Douglas's culdesac the tubes and ovaries are ligated with catgut and severed, and as much also of the broad ligament as is necessary to allow of the uterus being turned downward through the posterior vaginal opening and sufficiently inverted to close the gap in the floor of the bladder. The mucous and serous surfaces coming in contact with each other and intended for approximation are denuded and stitched together by interrupted silkworm-gut sutures. An opening is made through the wall of the uterus into the uterine cavity at a point corresponding with the location of the external meatus and a retention catheter inserted up through the dilated cervical canal into the bladder. The parts are approximated with sufficient firmness to prevent leakage from the now fully-constructed bladder. The vagina is loosely packed with iodoform gauze; permanent drainage is established by means of the catheter. The newly-formed bladder is washed out with a saturated solution of boric acid every eight hours and the external parts bathed with the bichlorid solution, followed with sterile water, and dusted with aristol or some antiseptic powder.

Medical News, August 9, 1902.

Physiology of the Pancreas.—Russell H. Chittenden says that as one scrutinizes the various results obtained by many investigators during the past few years, it seems probable that in the pancreas there must be certain specialized cells which manufacture an internal secretion; something which exercises a controlling influence on certain lines of metabolism in the body. When it is wanting, disturbance and distortion of the nutritional rhythm result. But while the pancreas has a marked effect on the metabolism of carbohydrate matter, and while disturbance of the gland, or any insult offered to it may result in temporary or permanent glycosuria, there are indications that some forms of so-called pancreatic diabetes are to be explained, not through a simple disturbance of the pancreas, but rather as the result of a physiological disturbance of the inter-relationship of several allied glands or structures.

Report of Two Cases of Temporary Hypertrophy of Glands of the Skin of the Axilla in Puerperæ.—C. S. Bacon has had two cases of swelling in the axilla appearing about the third day after labor. In the first case there were two masses, apparently in the skin; the axillary mass measured about one and one-half inches from side to side, and about two inches from below upward. The mass on the front of the chest over the pectoral muscles was about three inches broad from side to side, and two inches from below upward. There was very little discomfort, and it disappeared in three or four days. The second case was almost identical with the first, except that it disappeared five days after it was first noticed, on the ninth day of the puerperium, and then reappeared two days later, to remain several days more. Both cases were primiparæ. The The condition appears to be a hypertrophy of certain sepcialized sweat glands of the axilla that produces these masses in the skin.

Some Aspects of the Pathology of the Pancreas from the Standpoint of Recent Investigation.—George Blumer states that the work of Opie, and of Wright and Jeslin, has shown that in a certain proportion of cases of diabetes the islands of Langerhans are extensively changed, while the great mass of the gland is to all intents and purposes normal. It may be that the older writers who described the pancreas as without lesion in diabetes, failed to take these changes into account. On the other hand, the pancreas may be extensively destroyed without the occurrence of diabetes. This, according to Opie, is because there are two classes of pancreatitis—the interlobular and the interacinar. In the former, even when extensive, the islands of Langerhans are not involved. In the interacinar form they are gradually encroached upon and destroyed by the newly-formed connective tissue, but even here it is only late in the disease that they become extensively involved. It is, however, evident that the study of the islands of Langerhans in diseases of the pancreas, and in diabetes particularly, is yet in its infancy, or at least in its childhood, and it is reasonable to hope that further study will render still more clear this hitherto obscure field.

Note on the Administration of Water in Disease.—G. Frank Lydston concludes that while the ingestion of large quantities of water in various affections is often of great value, the treatment is sometimes extremely detrimental, causing impairment in the nutritive value of the blood by the relative hydræmia produced, disturbances of the circulatory and nervous systems, and serious digestive disturbances, involving impairment of the secretion and composition of the gastrointestinal juices, and gastromotor insufficiency. Œdema and anasarca, while often relieved by the free ingestion of water, are not infrequently increased by it. Renal water habit may develop, by virtue of which the kidney becomes permanently sluggish, unless it receives its wonted stimulus of large amounts of water. Acute and chronic inflammatory affections of the kidney are sometimes aggravated by giving water in excess, simply by overworking the renal organs. Inflammatory affections of the lower portion of the genitourinary tract are often deleteriously affected by excessive water drinking, through the mechanical disturbance necessituated by the resultant frequent and copious micturition.

New York Medical Journal, August 9, 1902.

Artificial Respiration in an Asphyxiated New-born Babe.—George W. Greene has devised a simple instrument, which consists of a rubber-bag with one-half of a rubber ball on the nozzle. To excite respiration in a case of asphyxia the ball is applied to the mouth of the baby, whose nose is held, and the bag is squeezed repeatedly until the lungs are filled.

The Vaccination Question.—Theresa Bannan thinks that, in spite of a century of evidence of the protective power of vaccinia, it is safe to say that not 1 per cent. of the children coming under the notice of the public vaccinator would be vaccinated were they not required to give evidence of its successful operation before they were admitted to school. Many parents object to it on the ground that they have known, or heard of, cases of disease or death which have followed the operation; others are opposed to revaccination. The paper deals chiefly with the various kinds of vaccine virus the writer has used and the method of performing vaccination.

The Successful Treatment of Hay Fever.—J. Wilkinson Jervey considers that the disease can be controlled by the removal of the three essentials that form the tripod of its existence, *viz.:* (1) A peculiar nervous susceptibility; (2) Some abnormality (a hyperæsthesia or a malformation, or both), perhaps apparently ridiculously trifling, in the nasal structures; (3) The presence of some individually irritating substance in the atmosphere. The local treatment advised is the application of an aqueous solution of suprarenal extract after a thorough spraying with an alkaline antiseptic solution alternately with a 10 per cent. solution of cocaine. A drop or two of the suprarenal solution may also be instilled into the conjunctival sac. The after-treatment, carried out by the patient himself, consists in spraying the nose three or more times a day with Dobell's solution, and in the internal use of three grains of suprarenal extract every three hours. The bowels should be kept very regular, and the diet should be simple. An excellent tonic and nerve food is the elixir of glycerophosphates of lime and soda.

A Fluoroscopic and Percussion Sign of Pleuritic Effusion Hitherto Undescribed; Report of Two Illustrative Cases.—Charles Lyman Greene presents a preliminary report, which is in brief as follows: (1) In unilateral pleural effusion the heart border corresponding to the opposite side shows a marked change in position as between full inspiration and full expiration, when the patient is sitting or standing erect; (2) This is easily demonstrated by percussion, sustained by the evidence afforded by inspection and apex auscultation, and absolutely confirmed, if necessary, by the fluoroscope; (3) Such a range of excursion does not occur in the normal chest or in those conditions likely to be confounded with pleuritic exudation; (4) The technique consists simply in percussing the free cardiac border in full inspiration, and again in forced expiration, with the patient in a standing or sitting posture, and noting the change of position. The border will be displaced outward by the expiratory movement; (5) Percussion of the upper border of flatness posteriorly shows a well-defined rise of the fluid in full expiration coincident with the outward displacement of the heart.

American Medicine, August 9, 1902.

A Case of Secondary Anæmia of the Pernicious Type Associated with Marked Jaundice; Rapid Recovery.—Eleanor C. Jones reports a case which is of interest because of the remarkable rapidity with which the alarming symptoms and grave anæmic changes in the blood developed, and because of the equal rapidity with which restoration was accomplished. The patient was admitted to the hospital January 10, and was discharged after an illness of only two months, the blood in that short time having undergone deterioration to a point that gravely threatened existence, and having afterward become so nearly perfect that on her discharge from the hospital, March 13, all the functions of life were properly and easily performed. The case is also interesting and unusual because of the grave and pernicious type of anæmia and other severe constitutional symptoms following in a case beginning as a simple one of catarrhal jaundice.

The X-Ray Treatment of Carcinoma.—Wallace Johnson and Walter H. Merrill report sixteen cases of carcinoma treated regardless of their length of existence, extent of tissue involved, and previous treatment received, and of these, ten patients, or 62.5 per cent. are apparently cured. In addition, four cases show improvement, and three of these give promise of ultimate recovery under further treatment. Only two cases failed to derive benefit from the treatment other than a leviation of pain and diminution of discharge. Seven additional cases of carcinoma were treated, all of which were classified as inoperable by the surgeons who referred them for treatment, and these merely had relief from pain—probably a temporary delay in the final fatal termination. From the table submitted it is seen that lupus vulgaris and superficial epithelioma or rodent ulcer hold out every prospect of complete cure by this treatment, whereas the deeper-seated carcinomas are at best merely relieved of pain and forcibly retarded in their progress. Fibromas show no change at all.

Epiphenomena of Cerebral Hemorrhage.—F. Savary Pearce describes the epiphenomena of the attack itself are the great arhythmia of the heart, and disproportionate high temperature on the paralyzed side of the body in cases of hemiplegia following apoplexy and continuance of extreme mental depression with lacrymosis. Sensory paralysis may persist on the palsied side, and there may be acute or chronic Bright's disease. No matter how apparently well the patient becomes after cerebral hemorrhage, it should be insisted upon that he is a disabled person, and must be cautious in conserving energy, especially of brain work. There should be interrogation as to specific disease, since these are the most fortunate cases in prognosis by the persistent use of iodides and mercury bichloride. The patient with fairly good arteries and nutrition passing the fifth year after the "stroke" will probably survive many years with the hemiplegic disability, provided the greatest care in hygiene is maintained. Occasional venesection is of value in preventing relapse. The frequent use of Kissingen or Carlsbad salts is of value through the depleting effect upon the overloaded blood vessels. Nitroglycerin, and static electricity dilate the vasomotor system and relieve the embarrassed circulation. Massage, hot baths, and Swedish movements, accompanied by the long spark of the static current, relieve the painful condition in the paralyzed parts due to an arthroneuritis.

Philadelphia Medical Journal, August 9, 1902.

A Case of X-Ray Dermatosis.—Linnaeus H. Prince described three attacks of dermatitis produced on his left hand by the use of the *x*-rays in examinations. Whatever the cause, there appears to be present a disturbance of the nutritive function of the part, associated with a chronic fibrosis in the tissue of the true derma. The later appearing desquamation was a part of the general process, from the changes in the nutritive areas of the skin. Local tissue necrosis with ulceration has never been a part of the process. Two attacks subsided while exposed to the influence of the conditions which induced them. Quite recently the author subjected both hands to the action of an excited Crookes' tube, and at once noted a sensation of irritability in the diseased member, while its fellow was uninfluenced.

Ascites with Abdominal Tumors.—A. Lapthorn Smith thinks that we may have ascites caused by an abdominal tumor in one or both of two ways: First, the tumor may be solid enough and free enough to rest upon the inferior vena cava and cause obstruction or back-pressure sufficient to cause serum to exude through the walls of the veins; or if the tumor is malignant it quickly affects the liver by metastasis and blocks the portal circulation, as well as the inferior vena cava passing behind it, causing back-pressure and exudation of serum from both the veins of the stomach and intestines, as well as from the inferior vena cava and its branches. The other explanation is that there is some irritant poison given off by a diseased ovary which either increases the secretion of the peritoneal surfaces or closes the mantles of the absorbents, which under normal conditions are able to carry off large quantities of serum in a few hours. The author agrees with Osler as to the importance of looking for an abdominal tumor in cases of ascites.

The Normal Third Stage of Labor, with Special Reference to Its Management.—Rudolph Wieser Holmes believes that in the management of the third stage we must adopt a compromise between the purely expectant and the Credé methods. The child is disposed of, the buttocks, vulva, etc., cleaned with antiseptics, fresh linen placed under the patient, and a sterile pad applied to the vulva. The cord is placed over one groin, the thighs being closely apposed to keep air from the vagina and promote retention and clottage of blood. The pulse is watched and the hand placed lightly on the uterus. In from 10 to 30 minutes, exceptionally an hour or more, the fundus will rise, and the cord advance. Now the placenta is outside the uterus, and further advance is to come from abdominal pressure, which is an uncertain factor. Vulva and vestibule are rendered sterile, and bladder emptied. The uterus will take a position in midline, or be brought there. Four fingers pass behind it, and raise it until its long axis is perpendicular to the plane of the brim. When it has reached the acme of its hardness, the thumb is flexed, which permits the hand to firmly hold the uterus, and with a downward movement the placenta is forced out by the upper segment, telescoping the lower. If this procedure is not hurriedly carried out the membranes will slowly escape.

The Lancet, August 2, 1902.

Chronic Sphenoidal Suppuration: Some Observations on Operation and Cicatrization.—David McKeown discusses the question as to what is the condition of the sphenoidal sinus when as the result of treatment it has ceased to be a discharging cavity. As a result of his experience with three cases in which he removed, in addition to the whole of the anterior wall, as much as he could of the floor, he has come to the conclusion that one cannot be sure that no secretion is penned up either in anatomical pockets or cicatricial pockets—*i. e.* pockets formed by the coalescence or contract of opposing granulations leaving cavities behind unlined by dry membrane. A cure may not thus have been effected, although for a considerable period there has been no discharge from the sinus.

The Simulation of Acute Peritonitis by Pleuropneumonic Diseases.—H. L. Barnard discusses the symptomatology, diagnosis, and pathology of a class of cases in which it is easy to mistake thoracic for abdominal disease. This deceptive likeness of two diseases is not of purely theoretical interest, for a mistaken diagnosis is often followed in such a case by an unnecessary operation. The thoracic diseases which can give rise to such severe abdominal signs as to simulate peritonitis are all situated in the lower part of the chest, either in the base of the lung or the adjacent pleura—diaphragmatic or parietal. Three of the author's cases were those of pleuropneumonia of the base of the lung, involving the diaphragm. Two were cases in which apparently a tuberculous focus in the apex of the lower lobe ruptured into the pleural cavity, producing pyopneumothorax. One case was most interesting in that the pleurisy was traumatic, due to a localized injury and associated with broken ribs; it was recognized, and yet the abdomen was opened, so definite were the abdominal signs.

Purpura Fulminans Following Scarlet Fever.—Herbert E. J. Biss gives a summary of the clinical and pathological features of a case of this kind, interesting not only because of its great rarity, but also on account of the difficulty of distinguishing it from hemorrhagic scarlatina. The child had a very severe attack of scarlet fever, which did not present any unusual features, and convalescence appeared to be established. He still had some ulceration of the soft palate, but the other symptoms had either passed off or had much abated, the temperature was settling down, and he was bright and comfortable. At this point cutaneous hemorrhages in enormous abundance took place, accompanied by hæmatemesis, bloody stools, and oozing from the gums. In thirty-six hours from the appearance of the first hemorrhages he was dead. The chief feature of the post-mortem examination was the state of the kidneys. These were transformed almost entirely into fat, a small blood clot being found in the calices. This blood clot must have been very recent, as none was found lower down the urinary tract, even the urine in the bladder being free from blood.

Deutsche medicinische Wochenschrift, July 17, 1902.

Surgical Treatment of Pulmonary Ulcerative Lesions.—Rudolf Riegner says that of all pulmonary ulcerative lesions, acute and subacute gangrenous processes are the most suitable for operative treatment. However, the lesion must be circumscribed, not multiple and located near the surface of the lung. Simple abscesses do not, as a rule, require surgical treatment. Chronic gangrenous, bronchiectatic, and tuberculous deposits, on account of their multiplicity, are not usually suitable for pneumotomy. For operative treatment an accurate diagnosis of the location of the lesion is absolutely necessary. In the absence of cavity signs such a diagnosis is possible if the three following conditions are established: (1) A circumscribed area of dulness surrounded by normal resonance; (2) the presence of shreds of lung tissue in the expectoration; (3) a Röntgen picture which shows a circumscribed lesion. Nine cases are reported in detail.

Massage and Leucocytosis.—Erik Ekgren has observed the effect of massage (general and abdominal) upon the number of leucocytes in the peripheral blood. The observations were made upon nine persons. Five of these received general and four abdominal massage. In all of the cases the leucocytes were increased in number (from 8.3 to 15.5 per cent.) following the treatment. As a rule, the increase reached its maximum ten minutes thereafter. In a few instances this period was increased to 20 or 25 minutes. The multinuclear leucocytes showed the greatest increase in number. Usually the most pronounced increase was observed following abdominal massage. It is, of course, impossible to say whether the number of leucocytes is actually increased or whether the cells are forced in increased numbers from the center toward the periphery of the body as the result of the massage, but the author is inclined toward the former view.

Septic Endocarditis Successfully Treated by Silver Injections.—C. L. Klotz reports a case of septic endocarditis, following a rheumatic attack, which was successfully treated by intravenous inoculations of silver. Three inoculations were given in an amount of 9.9 and 7 centigrams, respectively, in a 1 per cent. solution. At the time of the first inoculation the temperature was 39.2°C., and the pulse not countable. Two hours thereafter the temperature was 38.2°C., and the pulse 112. The improved condition lasted for about twenty hours when the alarming symptoms returned, and the inoculation was repeated to be followed by a similar favorable result. At the end of the next twenty-four hours a slight relapse occurred, the pulse reaching 98. The final inoculation given at this time sufficed to permanently relieve the symptoms. In view of the high mortality of this disease, the results obtained in this case are thought to be of the greatest interest.

Berliner klinische Wochenschrift, July 21, 1902.

Tetanus from Subcutaneous Injections of Gelatin.—Paul Krause reviews the literature relating to the development of tetanus following subcutaneous injections of gelatin which have been employed for therapeutical purposes. It is evident that such tetanus-infection is due to an insufficient sterilization of the gelatin used. The only method by the means of which a gelatin solution can be surely sterilized is that in use in bacteriological laboratories for the sterilization of culture media. This is known as the fractional method, and consists in exposing the gelatin to a temperature of 100° C. for half an hour on each of five successive days. This method should be employed in all hospitals and by all druggists for the sterilization of gelatin solutions for subcutaneous injections.

Topical Diagnosis of Ulcers and Tumors of the Stomach.—Karl Glaessner draws attention to the fact that both pepsin and the milk-splitting ferment are secreted in the fundus of the stomach, while in the pylorus only the former is produced. Observation has shown that this fact may be utilized in the topical diagnosis of ulcers and tumors of the stomach. The usual test meal is given and the stomach contents tested for the presence of these ferments. If both pepsin and the milk-splitting ferment are reduced in amount the fundus is the portion involved, while if pepsin only is reduced the pylorus is the seat of the lesion.

Münchener medicinische Wochenschrift, July 22, 1902.

Loss of the Patella Reflex in Lobar Pneumonia in Children.—Meinhard Pfaundler has examined fifty-five cases of lobar pneumonia occurring in children under ten years of age with respect to a loss of the patella reflex. In children of this age who are attacked by lobar pneumonia this reflex is very frequently reduced or entirely absent. Oftentimes this sign is present before the appearance of characteristic local symptoms. In positive cases it is of great value in the differential diagnosis between meningitis and lobar pneumonia.

Myxoma of the Ovary.—Carl Hennig reviews the symptomatology of the sixty cases of gelatinous cysts of the ovary which have hitherto been reported, and adds the personal observations of another case. The patient was sixty years of age and had suffered with the tumor for about seven months. Pain was a prominent symptom, and in this respect the case differs from the majority of those which have been observed. During the operation the cyst was broken and about six liters of gelatinous material thus evacuated. It was found impossible to remove all of the cyst wall, and hence the wound was loosely packed with gauze and allowed to drain. Recovery followed, and no recurrence has as yet taken place, the operation having been done in October, 1901. The gelatinous material evacuated contained many plasma cells and hyaline bodies.

French and Italian Journals.

Syphilitic Genital Chancre.—Renault states that the diagnosis of syphilitic chancre is far more difficult in reality than at first appears. The more one sees of chancres the more does their diagnosis seem beset with difficulties. In a great number of cases, therefore, it would be prudent to reserve judgment on the nature of the lesion, until the diagnosis can be made with absolute certainty. The author then reviews certain anomolous forms of the chancre. The characteristics of the classical lesion are superficial loss of substance, a rose-colored base with a slight secretion resting on an indurated zone.—*La Tribune Médicale*, June 9, 1902.

The Intravenous Injection of Oxygen in Man.—F. Mariani, from his experimentation, concludes: (1) That oxygen injected into the veins is completely absorbed by the red blood cells, and therefore does not cause gaseous emboli; (2) The injection should be done slowly, so that not more than 500 c.c. of oxygen will be injected in the course of an hour, in order that all of it may have time to be absorbed; (3) Intravenous injections of oxygen are indicated in all cases in which pneumatosis is threatened, their immediate and pronounced action being due to the increased production of oxyhæmoglobin.—*La Riforma Medica*, July 19, 1902.

The Poison of Glanders.—From his researches Angelo Marc-Antonio reaches the conclusion that the serum of animals suffering from acute glanders, from which the bacilli have been removed by a Chamberland filter, does not, when injected in healthy animals, provoke the formation of specific nodules in the parenchymatous organs. This is the opposite of what occurs in tuberculosis. But it does cause fatty degeneration of the liver, interstitial pneumonia, and a destruction of red blood corpuscles, as shown by the accumulation of hematic pigment in the spleen. Therefore it is evident that in contradistinction to the dead bacillus tuberculosis, which can reproduce tuberculosis, the cadaver of the glanders bacillus cannot reproduce the glanders nodule.—*Giornale Internazionale delle Scienze Mediche*, July 15, 1902.

Fibroadenoma of the Breast.—Brin and Papin describe this interesting tumor, which occurred in a woman fifty-eight years old. The growth had been of long duration, as it had been increasing in size gradually for more than ten years. It had never been painful, and was only annoying from its weight. When it was not supported, the tumor reached to the thigh. It was attached to the wall of the thorax by a long and loose pedicle. Its extirpation was very easy. Between it and the thorax there was loose, cellular tissue. Histological examination showed the growth to be an adenofibroma. The entire mammary gland was transformed into the tumor. It was hard to cut, as there was a considerable amount of calcareous salts in its tissues. The size of this tumor is rarely attained by any but a sarcoma.—*Bulletins et Mémoires de la Société Anatomique de Paris*, February, 1902.

A Note on Simple Hypertrophy of the Liver in Pernicious Anæmia.—A. Gilbert and M. Garnier report another case of pernicious anæmia, in which the liver was increased in volume without being the seat of very serious microscopical alterations. It was a case of simple hypertrophy of the liver. There was a little infiltration of very fine ferruginous particles limited to the periphery of the lobule and not appearing to disturb at all the function of the cell. There were also minute areas of necrosis analogous to those noted in experimental anæmia, and seen only on the closest examination. But most of the cells were normal. Hypertrophy of the parenchyma constitutes the principal alteration in certain cases of progressive, pernicious anæmia.—*Le Bulletin Médical*, July 9, 1902.

Muscular Interposition in the Treatment of Osseous Ankylosis.—Nélaton declares that the treatment of ankyloses is sometimes very difficult, and the reestablishment of function in an articulation which has become ankylosed is not always obtained by an osteotomy or by resection. As in a case of fibrous ankylosis of the thumb in which resection was rewarded by a good degree of motion, nevertheless this result did not prevent a second ankylosis taking place in two months. Nélaton praises a method which consists in interposing, after resection, a muscular band between the bony surfaces. He reports two interesting cases. The first was a patient with ankylosis of the hip following acute rheumatic polyarthritis. After resection the operator interposed a large muscular band between the surfaces. Two years afterward, although the patient limped, nevertheless he could stand upright and he could take long walks and he had the movements of flexion, abduction, and rotation to a marked degree. The second patient had ankylosis of both hips. The same treatment procured for him mobility of the joint.—*Journal des Praticiens*, July 5, 1902.

Bulletin of the Johns Hopkins Hospital, July, 1902.

The Surgical Treatment of Tuberculous Cervical Adenitis.—James F. Mitchell concludes, from the study of his own cases and from the results of others, that: (1) Tuberculous cervical adenitis is primarily a local disease of very frequent occurrence, more often in young persons; in itself not extremely serious and rarely, if ever, proving fatal; (2) It bears, however, a certain definite relation to tuberculosis of the lungs, and serves as the starting point from which tuberculosis may spread; (3) The tuberculin test as an aid to diagnosis is positive and harmless; (4) While recovery may often take place under good hygienic conditions, surgical interference is clearly demanded in most cases; (5) When surgical treatment is resorted to the operation should be radical in all cases; (6) Recovery may be predicted in 70 to 80 per cent. of cases so treated. Tuberculosis of the lungs after complete removal of the glands is comparatively rare; (7) Tuberculosis of the lungs, unless far advanced, is not a contraindication to operation, the removal of the glands apparently exerting a beneficial influence on the condition of the lungs.

The Leucocyte Count in the Summer Diarrhœas of Children.—J. H. Mason Knox, Jr., and Louis M. Warfield summarize the results of their investigations as follows: (1) A differential count of leucocytes in the blood of well children under two years of age, when compared with the blood of adults, shows that there is a relative increase in the small mononuclear elements and a decrease in the number of polymorphonuclear cells; (2) In the summer diarrhœas of infants the number of leucocytes in the blood is usually increased, but the count of the white cells varies within such wide limits, even in the milder forms of the affection, that a high or low leucocytosis cannot be regarded as of diagnostic value; (3) In the simple dyspepsias of childhood a differential count of the leucocytes does not show any marked variation from that of a healthy infant, but, as the cases become more severe in type, there is apparently a progressive increase in the polymorphonuclear neutrophile cells and a decrease in those of the small mononuclear variety, thus presenting a picture more like that of adult blood; (4) As pointed out by Japha, the polymorphonuclear leucocytosis is an indication of an intoxication with decomposition products in the intestine or of the toxins of pathological bacteria, *i. e.* it takes place both in the cases of acute intestinal poisoning and in the more severe forms of ileocolitis; (5) The cases of simple infantile atrophy present a nearly normal differential leucocyte count, but it would seem that an increase of the polymorphonuclear cells may indicate the setting in of an inflammatory intestinal complication.

Typhoid Fever; Report of a Case with Three Relapses; Remarks.—Louis M. Warfield, after describing a case of typhoid fever with a history of three relapses, states that a relapse is never caused by external and exciting causes alone, such as sudden emotion, etc., but it is due to a reinfection of the organism with the typhoid bacillus. He then discusses Durham's new theory of the etiology of the typhoid relapse. He assumes that an infection is a complex phenomena, due to the infection with the varieties and subvarieties of the infecting agent, no one of which is identical with or equivalent to any other one. Each kind is assumed to have its corresponding antibody formed in the blood. Probably a pure infection never occurs. If the different antibodies are called forth in sufficient number to take care of the toxins of the different varieties the organism recovers and no relapse occurs. If the varieties are remote there will be a preponderance of certain groups of antibodies, but a scarcity of others, so that if the corresponding bacteria to the latter start to grow, there will be a reinfection as there are no antitoxins in the blood corresponding to these toxins. On this theory multiple relapses can be readily explained. This theory is more adequate than any yet advanced, and it suffices as a working basis.

The American Journal of the Medical Sciences, August, 1902.

A Case of Hyperplastic Tuberculosis of the Vermiform Appendix.—Thomas R. Crowder believes that secondary tuberculosis of the vermiform appendix is a frequent condition, and usually occurs by extension from the cæcum. Primary tuberculosis of the appendix is a rare disease. The tuberculous appendix may undergo hyperplastic changes similar to those occurring in other parts of the bowel, chiefly the cæcum. Hyperplastic tuberculosis may be limited to the appendix, but such limitation is rarely met with. The etiology of tuberculosis as a distinctly hyperplastic process is not well understood.

Spontaneous Non-Tuberculous Pneumothorax.—M. H. Fussell and David Riesman state that: (1) Spontaneous non-tuberculous pneumothorax occurs in healthy individuals, but it is rare. It is most common in young men; (2) The pneumothorax is simple, *i. e.* there is no formation of fluid; (3) There is rarely any febrile reaction, except, perhaps, in the very beginning; (4) There is probably a moderate amount of emphysema in the lung, which is not recognized during life and is not incompatible with health; (5) Aspiration is a certain and safe means of relief, and should be resorted to in severe or prolonged attacks; (6) This form of pneumothorax is benign. All but one of the reported cases recovered, and only once was there formation of fluid.

Paratyphoid Fever; Report of Four Cases; Analysis of All Reported Cases.—William B. Johnston concludes that: (1) There is a type of disease due to infection with the paratyphoid bacilli which in all its variations presents a clinical picture identical with that frequently produced by infection with B. typhosus; (2) Diarrhœa and a termination of the fever by crisis are apparently of more frequent occurrence than in typhoid fever; (3) Myositis and purulent arthritis, rare complications in typhoid fever, have been recorded; (4) Though the disease may be severe, it is usually mild, and fatal cases are rare; (5) Absence of intestinal ulceration may prove to be a distinctive feature of the disease; (6) The disease, though widespread and occurring in localities where typhoid fever is present, is comparatively rare; (7) Every instance of negative Widal reaction is not due to infection with paratyphoid bacilli.

Paracolon Infection, Together with the Report of a Fatal Case, with Autopsy.—Warfield T. Longcope declares that broad conclusions cannot be drawn from one or two cases, but, if later pathological findings confirm the results so far obtained, the distinction, made on a bacteriological basis by various observers between these infections and typhoid fever, will be fully confirmed by anatomical evidence. The wide distribution of the bacillus in the body; its constant occurrence in the circulating blood, and the absence of any localizing lesions, all point to the fact that the condition is simply one of general infection. Typhoid fever, as a rule, is now considered a general infection with localized lesions and not a local disease, so it is not surprising that the symptoms of these two affections are so similar. There is a close relationship between the B. typhosus and the paracolon bacillus. Possibly later on a closer connection between the paracolon infections and typhoid fever will be discovered. However, it is now known that the paracolon bacillus can produce a fatal infection distinct from typhoid fever.

Report of a Case of Paratyphoid Fever.—Albion Walter Hewlett, after reviewing some of the late work on paratyphoid fever, reports a case. The patient was a stoker, thirty-four years old, who presented all of the essential clinical features of enteric fever except the presence of a palpable spleen and a Widal reaction toward typhoid bacilli. It is possible that the spleen was enlarged, but was not palpable on account of the distention. On the ninth, nineteenth, and thirtieth days, the blood serum agglutinated typhoid bacilli fairly well, but not typically, in a dilution of 1 to 10. No agglutination occurred in a dilution of 1 to 50, and no intermediate dilutions were used. There was a rise of the fever after several days of normal temperature, and on the fourth and tenth days of the second fever. The first and last cultures were negative in result. On the second occasion one flask showed a growth of a bacillus called for convenience B. "Noonan." The patient's serum agglutinated this organism in a dilution of 1 to 100. The B. Noonan is a short bacillus decolorizing by the Gram method. In early bouillon cultures most of the organisms are motile, the movements being more darting than those of the typhoid bacilli. The organism differs also from the typhoid bacillus in that it produces gas in glucose, and does not cause a diffuse clouding of the Hiss semisolid medium. It differs from the colon bacillus in not fermenting lactose, not coagulating milk, and not, at least readily, producing indol. The results of the agglutinating experiments, with typhoid bacilli, have been given above.

A Case of Hemorrhagic Exudative Erythema (Henoch's Purpura).—Herbert Swift Carter reports this case, which was one of a modified form of Henoch's purpura. The patient was a woman aged twenty-nine years. The interesting points in this case are: (1) At first apparently an ordinary attack of rheumatic purpura, with typical eruption and joint symptoms, preceded by sore throat; (2) Excessive amount of indican in the urine at first, later never more than a trace; (3) Temperature, pulse, and respiration never above normal; (4) No hemorrhage from visible mucous membranes; (5) Very severe abdominal pain, limited to the upper half of the abdomen and usually most marked over the stomach area, which began shortly after the appearance of the skin eruption and increased in intensity, reaching its climax when the eruption was most marked, except for the slight modification in the last relapse, when the pain was most severe just before the eruption was at its height; (6) Relapses three to ten days apart. The entire illness lasted for three and a half weeks; (7) No hyperleucocytosis; (8) The course of the disease and relapses and pain were uninfluenced by salol, salicylates. ergot, gelatin, acetanilid, iron, bismuth, alkalis, aqua, chloroform, calx chloride, and poultices, all tried in various ways. The pain was only relieved by morphine. It seems fair, the author believes, to place this case among the exudative erythemas associated with purpura and gastrointestinal crises (Henoch's purpura). The intestinal hemorrhages in Henoch's series were presumably due to the purpuric eruption on the intestinal mucous membrane, and although in the case here reported there was no intestinal hemorrhage and only a slight streak of blood in the vomitus during the second relapse, still the writer thinks that the intraabdominal symptoms were in all probability due to an eruption, either purpuric, exudative, or both, into the gastric or intestinal mucous membrane.

Russki Arkhiv Patologii, etc., June 30, 1902.

A Contribution to the Study of Glioma of the Brain.—W. A. Mouratoff reports a case of a woman suffering from cephalalgia, vomiting, and complete blindness. The disease began acutely a week and a half after her menstrual period. with unconsciousness and an epileptiform attack two months before her admission to the hospital. Aphasia and complete paralysis of the lower limb followed, and death occurred with symptoms of general marasmus. At the autopsy multiple hemorrhages and softening of the left frontal lobe were found. The microscopical examination showed that there was a glioma. The whole of the anterior commissure was found to be dotted with granular black globular bodies. The case, therefore, proves that degeneration of the anterior commissure follows focal destruction of the white matter of the frontal lobes.

The Pathological Anatomy and the Pathogenesis of Syringomyelia.—P. A. Préobrazhensky, in the examination of four cases, found that in each the primary cavity was found by a dilatation or a diverticulum of the central canal. The cavity was lined with epithelium. Obliteration of the cavities is a constant symptom of gliomatous syringomyelia, and it may be partial or complete, according as the bundles of neuroglia partly or entirely fill the cavity. This proliferation of neuroglia is not identical with glioma. The initial stages of the disease may long be latent, and so may even the advanced stages, so that the original cause (hematomyelia neoplasms, traumatism, infectious diseases. chronic pachymeningitis, etc.) is always uncertain. In true syringomyelia there is always some anomaly of the central canal, with the formation of caverns from gliomatous softening and disintegration.

The Plague at Batoum in November, 1901.—N. Bérestneff states that the bacillus of plague was isolated from a patient and was found to be extremely virulent and in every way character stic. Plague bacilli usually perish in the bubo or about the fourteenth day of the disease in cases unaccompanied by septicæmia and with a fall of temperature on the eighth and ninth days without specific treatment. The cultures may or may not be viscid. In the case under consideration, the colonies were round, projecting, and whitish in color. The charasteristic colonies of plague, surrounded by a transparent zone, were found only when oxygen was deficient, or when the growth of the colony was in any way retarded. Cultures of the plague bacillus easily became desiccated, but those taken from the blood or the exudate resist longer than those cultivated in the ordinary media. If preserved in blood or peritoneal exudate in sealed tubes. they undergo the same morphological changes as in the organism. Plague bacilli mixed with other microbes can easily be demonstrated by means of the stalactites and superficial pellicles which they form in a bouillon culture. In suspected cases, when the bacteriological result is negative, tests should be made for agglutination, which is a specific reaction.

Disease of the Muscle of the Heart.—H. W. Syers writes of the cause and detection of this affection, and in regard to the treatment says that the right management consists in regulating the mode of life, both as regards physical and mental exertion and diet. Those whose hearts are unsound in the sense here considered are not fit subjects for active exercise, and are totally unfit for training by mechanical movements (dumb bells, etc.). Horse exercise, a well-manned cob being selected, is the kind of exertion most suitable to these patients, and, failing this, they must be content with walking. Graduated exercises and warm baths, so much in vogue as a method of treatment, the author considers to be highly dangerous when the heart muscle is affected. Hot baths are likely to cause fatal syncope. Food should be moderate in quantity, and the meals should be not too far distant the one from the other. Nitrogenous food is preferable to a carbohydrate diet, and but little fluid should be taken at meals. A moderate amount of stimulant is sometimes desirable. Smoking is almost always injurious. Constipation is often a troublesome symptom, and should be overcome by enemata and small doses of cascara sagrada, and aloin, with anoccasional mercurial purge. Heart stimulants do more harm than good, but nux vomica and strychnine in very small doses tend to promote the appetite and to increase the peristaltic action of the intestines.—*Treatment.*

Cultivation of the Virus of Variola.—T. Ishigami concludes, from his researches, that certain protozoa found in the epithelial cells of dissected preparations of vaccine virus are the active agents in the causation of variola. They belong to the sporozoa Their growth is not restricted to the interior of cells, as has been believed heretofore. They can be cultivated in a special medium made with epithelial cells of a non-vaccinated animal. By inoculating a calf with this artificial culture we get vaccine vesicles accompanied by fever in from three to four days or less. These vesicles do not differ in the changes they excite nor in the kind of sporozoa which they contain from those produced by the inoculation of ordinary vaccine lymph. The calf, once inoculated with this artificial culture, is completely minimized against the vaccine virus. By inoculating other calves with the lymph from the vesicle formed by this culture we can get regular vaccine vesicles possessing protecting power against variola. It is, therefore, clear that these sporozoa are the originators of variola.—*The Sei-I-Kwai Medical Journal.*

Pericardial Friction Sound Extensively Propagated.—E. Devic and J. de Teyssier state that the non-propagation of the pericardial friction sound is generally considered as an important element in the diagnosis. They, however, report a case of their own and several of other observers in which the sound was transmitted to a considerable distance. Several factors are concerned in this transmission of the pericardial sounds. In the first place, the abundance and consistency of the pericardial exudates, the size of the heart and the energy of its contractions, and finally, the density of the tissues situated between het pericardium and the listener's ear. The intermediary good conductors are the skeletal bones, the liver and the lung tissue which is compressed, congested or hepatized. The subject is one that demands further investigation.—*Archives Générales de Médecine.*

The Language of Pain.—B. E. Dawson urges a more attentive study of painful symptoms as a guide to diagnosis. External pains frequently inform us of organic changes or deranged function of internal viscera; pain in the auditory canal or the upper portion of the anterior part of the external ear speaks in no uncertain sound of a different cause from pain in the back part or anterior and lower portion of the ear. Pain upon the scalp may be an expression of the fifth nerve, or the great or small occipital. Pain between the shoulders or over the inferior angle of the scapulæ may not be rheumatism, or cold, or neuralgia, but a message from the abdominal viscera, due to the connection between the great splanchnic, and the fourth, fifth, and sixth dorsal nerves. Pain over the stomach may mean spinal disease. Examples could be multiplied, but enough has been said to suggest that pain should not be too hastily lulled by opiates, but studied carefully, and. of course, relieved as well.—*The Kansas City Medical Record.*

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventieth Annual Meeting, Held at Manchester July 29, 30, 31, and August 1, 1902.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

Tuesday, June 29—First Day.

THE seventieth meeting began officially on Tuesday, but on Monday evening there was a formal opening of the annual exhibition (the thirty-fifth of the kind—by the Lord Mayor of Manchester, Mr. Alderman Hoy. This was held in the Drill Hall, which was prettily decorated and fairly filled with exhibits. There was a good attendance. Dr. Woodcock, chairman of the exhibition, introduced the Lord Mayor, who made a brief speech and declared the exhibition open. Afterward the audience was entertained with music, instrumental and vocal.

At 9.30 A.M. on Tuesday there was a meeting of the 1901–2 council, which, of course, was private. In the forenoon there was a service in the Cathedral, when Bishop Thornton preached the sermon. Simultaneously there was a service in the Roman Catholic Church, where the Rev. C. Coope preached.

The Bishop took for text "Neither shall there be any more pain," and spoke of the profession as dear to the heart of the people, and as having, among other things, by God's help, given them back their King. Contrasting the beliefs of Epicurus and Zeno in regard to pain, sickness, and death, he said the one made toward pessimism; the other toward optimism. Turning to Christian belief, he recognized death and pain as evils of themselves, and their alleviation and elimination as the ultimate purpose of God and the legitimate aspiration of God-like men. They were penal, remedial, and preparatory, but were tempered by self-preservative instincts, philanthropic sympathy and medical science. A collection for the Benevolent fund and college was made.

Mr. Coope discoursed on the relations between laymen and doctors. He said there were two attitudes toward the doctor, one of credulity, the other of superstition. Young, healthy people sometimes professed unbelief in medicine. That was foolish, and due to inexperience. To such he pointed out the King's case. The function of the physician was similar to that of the priest, and the two greatest sciences were theology and medicine. Turning to the other attitude, he said superstition was common as to both religion and medicine. It was possible to put up prayers to God which were obviously absurd and to make demands on the physician which were equally absurd. He counselled honoring the physician—expecting much from him, but not all.

In the afternoon the first general meeting was held in the beautiful Whitworth Hall, which is an extension of Owens College.

Address of the Retiring President.—The retiring President, DR FERGUSON, took the chair, and in opening the proceedings said this had been a very eventful year. It was to have included the coronation, but instead of that it included the King's grievous illness, over which the whole civilized world watched with trembling sympathy. But the year also included the King's happy recovery, which his Majesty owed to his own courage and the skill of his professional attendants. These attendants were most of them members of the Association, and their triumph was a triumph for the Association as well as for the art for which they lived and which had brought them together that afternoon. Therefore, the universal joy was theirs in a special degree at the recovery of their august patient.

Induction of the New President.—DR. FERGUSON then introduced his successor in the chair, Mr. Walter Whitehead, Consulting Surgeon of the Royal Infirmary, as a man who would confer as much honor on the Association as that Association could confer on him, for the great Manchester surgeon, he said, was known throughout the world as one of the rare original minds in surgery.

MR. WHITEHEAD then took the chair and said his first duty was to ask the meeting for a vote of congratulation to the King on his marvellous recovery. When he reminded them that his Majesty was the patron of the Association, he felt that they could not commence their ordinary proceedings without discharging that as their first and most pleasant duty. He proposed to send the following telegram. "That the loyal congratulations of the members of the British Medical Association, assembled in annual meeting, in Whitworth Hall, Owens College, Manchester, be respectfully offered to his Most Gracious Majesty King Edward VII upon his recovery from his serious illness, with an earnest prayer that he may long be spared to reign over a devoted empire." This telegram was unanimously approved and then dispatched.

A vote of thanks was passed to Dr. Ferguson for ably presiding over the Association during the past year and he was elected a vice-president for life.

The Report of the Council was then presented and adopted. In it the council expressed a conviction that the seventieth meeting would prove memorable in the history of the Association not only as a most successful one, owing to the efforts of the local members, but also as the first meeting after the greatest changes which had been made in the constitution of the Association since its foundation. The council trusted these changes would increase the influence of the Association and enable it to carry on its scientific, social, medico-ethical, and political work more readily. During the year 212 members died, 478 resigned, 1,046 were elected. The number now on the register was 18,758. The council noted with satisfaction the honors conferred on members, and especially congratulated Sir Victor Horsley, whose work in the Association the council gladly acknowledge. The income for the year was £43,730; the expenditure £37,767, leaving a surplus of £4,963 which was applied to reduction of the mortgage debt, now standing at £5,000. This year a second and further sum of £100 had been granted to the Special Chloroform Committee for the purpose of investigating methods of quantitatively determining the presence of chloroform in the air and in the living body. The sum of £375 was voted for scientific research and £650 for scientific research scholarships. The total amount which had been spent in scientific research through this Committee since its institution in 1874 was £17,023, independently of £1,650 granted to societies and bodies outside the Association. The interest taken by members of the Association in the subject of contract practice had been reflected in the pages of the official journal. The papers and discussions published from time to time have, it was noted, contained many valuable suggestions for remedying the evils generally admitted to exist, and much information as to the conditions prevailing in different parts of the country had been collected. The council reported with satisfaction that the bills in Parliament for projected tube railways in London which threatened the premises of the Association had been thrown out. It would be difficult, if not impossible, to obtain another freehold site so conveniently situated in so important a thoroughfare as the Strand. A committee having reported to the council on the subject of preliminary general education for those entering the medical profession, the council recorded the steps taken during the year with a view of raising the standard. A record was also given of the action taken by the Parliamentary Sub-committee with regard to the Public Health Bill, vaccination, the reorganization of the Army Medical Service, the Midwives' Bill, and the amendment of the Coroners' Act

MR. ANDREW CLARK, F.R.C.S., the retiring treasurer, moved the adoption of the financial statement for the year. He estimated the income and expenditure for the coming year as both increased, but he would be satisfied with a profit of £2,000 or $3,000.

Dr. Brassey Brierly took exception to the estimate, and said there was no justification for expecting an additional income from subscriptions, for the increase, if obtained, promptly went to the branches. He hoped the new organization would be for the welfare of the Association, but they must not picture too rosily what they might never attain. The report admitted they could not estimate accurately; he agreed with that and regarded the tremendous cost of working the new constitution as a speculation. He, therefore, urged caution.

Mr. Clark replied that the money received from increased subscriptions would go to the branches, but if it did not come in it would not go out. He felt justified in anticipating that it would come in, and he expected an increase of members, although some would resign. The resolution was passed. A vote of thanks was accorded to Mr. Clark for his services during the last three years. He was elected a vice-president, and Dr. Markham Skerritt was elected treasurer in his place. The meeting then adjourned until evening.

The Lord Mayor presided at the adjourned meeting and made a short speech of welcome. A number of visitors were presented and then Mr. Whitehead delivered his Presidential address, which was followed by a soirée in Owens College, given by the President and local committee.

Presidential Address.—Mr. Walter Whitehead took as the subject of his address the medical history of Manchester. The British Medical Association had met in Manchester just a quarter of a century ago, at which time the medical school had only just been amalgamated with Owens College, of which it has ever since been one of the most important departments. The day this address was delivered was the twenty-sixth anniversary of the death of John Owens, and the speaker asked his hearers to join with him in honoring the memory of one who was among the first in this country to show an appreciation of the fact, now so widely recognized, that the prosperity of a community, as of a nation, must have for one of its foundation stones a true respect for learning and intellectual inquiry, and an ardent desire to place the advantages of education within the reach of all who are capable of profiting by them.

Many had passed away who took an active part in the meeting held twenty-five years ago in Manchester. Dr. Eason Wilkinson, the President; Sir William Roberts, who delivered the address in medicine; Edward Lund, who was President of the Section of Surgery; Bradley, one of the secretaries of that Section; Leech, one of the local secretaries for the meeting, had all joined the majority. Dr. Eason Wilkinson, who welcomed the Association to Manchester from the presidential chair twenty-five years ago, devoted his address to a consideration of the principles of hospital construction, and pointed to improvements which, he urged, should be made in the Royal Infirmary. This was one of the last public acts of Dr. Wilkinson's life. Sir William Roberts, in his address in medicine, discussed the doctrine of *contagium vivum* and its application to medicine. He pointed out that it was the distinguished merit of Lister to have perceived that infective-wound diseases came from without. He protested, however, against confusing the broad principle that it was the duty of the surgeon to prevent infection of the wound, by a blind following of the method devised to achieve this end by Professor Lister. At the present day it might seem remarkable that so acute a man as William Roberts perceived no alternative between the application of antiseptics to the wound and a system of free drainage which enabled the surgeon to ensure that the poisonous products of infection were discharged, and thus avoid the occurrence of septicæmia through the absorption into the system of these poisonous products. It was the ideal of the antiseptic surgeons of that day to find an unirritating antiseptic, but it is now recognized that the quest was mistaken, and that in absolute surgical cleanliness of the patient's skin, purity of the surgeon's hands, and an aseptic condition of his dressings we have the true ideal. Sir William Roberts was the first Professor of Medicine in Owens College, and for nearly thirty years a member of the medical staff of the Royal Infirmary.

Mr. Whitehead then spoke of the beginnings of the educational and medical institutions of Manchester. First probably, in point of time, as well as in intrinsic importance, came the Royal Infirmary, which was at once a general hospital, an isolation hospital for those ill with infectious diseases, and a hospital for lunatics. It began just one hundred and fifty years ago when Charles White fitted up a small house. The needs of the city soon outgrew this modest building, and a plot of ground was purchased on which the present institution stands. The first building erected in 1755 had accommodation for forty patients. Ten years later a wing was added for the reception of patients with mental diseases. In 1796 a building was erected to serve as an isolation ward. The speaker then referred to the other hospitals in Manchester, and in particular to the new sanatorium for poor consumptives, now under course of construction at Bird Hill in Delamere Forest, the gift of Mr. Crossley.

Passing to the theme of medical education in Manchester, the beginnings of a medical school in that city were due to Charles White, the founder of the infirmary, in 1786, assisted by his son, he began a course of lectures on anatomy and physiology. Thomas Henry gave concurrently a course of lectures on chemistry. Henry, who had become a visiting apothecary to the infirmary in 1778, was one of the founders of the chemical industry in Manchester, and the discoverer of an improved method of manufacturing magnesia alba, called after him Henry's magnesia.

Dr. Ferriar, Dr. Roget, Mr. Ainsworth, and Mr. Ransome also took part in the courses given at the Infirmary, but Mr. Joseph Jordan was the real father of the Manchester Medical School. In 1814 he commenced the systematic teaching of practical anatomy in Manchester. He was assisted by Dr. Hull, physician to the Lying-in-Hospital and a botanist of distinction, and by Mr. Brigham. Their school began with four students, but the course was practical from the first. The foundation of the first complete medical school in Manchester was due to the energy of Mr. Thomas Turner, who, during his life of eighty-two years, accomplished a great work for medical education. In 1822 he began a course of lectures on human anatomy, physiology and pathology before the Manchester Literary and Philosophical Society. Encouraged by the interest shown in these lectures, he put forth, two years later, a scheme for a school of medicine and surgery. The school was started in a house in Pine street, and John Dalton, one of the most illustrious names in the intellectual history of Manchester, gave the lectures on pharmaceutical chemistry.

The school was recognized in 1825 as a fully-equipped medical school by the Royal College of Surgeons of Edinburgh, and is therefore the oldest as well as the largest of the great provincial medical schools of England.

Other medical schools were established from time to time, and flourished for a season, but the original one, founded by Turner, which later bore the title of the Royal Manchester School of Medicine, continued, and was largely influential in bringing about the foundation of a university college in the city, through the benefaction of John Owens. This foundation, the Owens College, broad in its conception, though small in its beginnings, has grown with the growth of Manchester, and with the increased love of knowledge and learning, until it is now one of the greatest educational institutions in Great Britain. The Medical Faculty has steadily grown in numbers and importance since it first formed part of the Owens College. In 1872-73, when the amalgamation took place, the medical students constituted 28.45 of all those studying in the College. In 1883-84 the proportion rose (excluding the women's department) to 40.8 per cent., and in the last two years to over 42 per cent.

Mr. Whitehead then spoke briefly of some of the Manchester physicians who had done great works in their day and generation. One of the first of these was Thomas Percival, a physician remarkable not only for his scientific attainments and benevolent character, but also for the breadth of view and width of culture which made him a pioneer in many movements, the effects of which were felt not only in the Manchester district, but throughout the whole country. He was the first president of the Manchester Literary and Philosophical Society, and also took a leading part in a movement which foreshadowed the establishment of technical schools, for he was one of the founders of the College of Arts and Sciences, at which courses of lectures were given on (1) Mathematics and Natural Philosophy; (2) Fine Arts; (3) Chemistry, with reference to arts and manufactures, and (4) the "origin, history and progress of Arts, Manufactures, and Commerce, the commercial laws and regulations of different countries, commutative justice, and other branches of Commercial Ethics." He was the author of a book on "Medical Ethics," which had its origin in a set of rules for the guidance of the staff of the Infirmary, and in their preparation he had the assistance of Dr. Ferriar and Mr. Simmons. To these rules Percival afterward added a series of chapters defining the course which should be pursued by practitioners in private practice toward each other and toward their patients. His labors to increase the welfare of the people made him a pioneer of sanitary reform and one of the earliest advocates of factory legislation.

In his endeavors to improve the sanitary state of the working classes, Percival had an able and eloquent helper in Dr. John Ferriar, a man of considerable literary attainments and learning, but especially a sanitarium of broad and advanced views, who advocated many reforms in the housing of the poor and the hygiene of their lives. In concluding his address, the President quoted the following words of Lord Bacon, written three centuries ago, in his preface to the Elements of the Common Laws of England, which expressed aptly the sentiments which should actuate the medical man of to-day: "I hold every man," said Bacon, "a debtor to his profession; from the which as men, of course, do seek to receive countenance and profit, so ought they of duty to endeavor themselves, by way of amends, to be a help and ornament thereunto. This is performed, in some degree, by the honest and liberal practice of a profession; when men shall carry a respect not to descend into any course that is corrupt and unworthy thereof, and preserve themselves free from the abuses wherewith the same profession is noted to be infected; but much more is this performed, if a man be able to visit and strengthen the roots and foundation of the science itself, thereby not only gracing it in reputation and dignity, but also amplifying it in profession and substance."

On the motion of Mr. Bryant, seconded by Dr. Alexander of New York, a vote of thanks was accorded for his address to the President, who in his turn proposed a similar acknowledgment to the Lord Mayor for taking the chair. This was carried by acclamation and briefly acknowledged.

Wednesday, July 30—Second Day.

The new council met 9.30 A. M. and elected Mr. Andrew Clark chairman. The sections met at 10, and when they separated they fund a notice posted cancelling the succeeding general meetings. It was said all the important business had been transacted at the first meeting. Others said the delegates under the new constitution had not met and they must appoint the business. Very few cared anything about it. There were two garden parties on hand, a number of excursions and unbounded hospitality.

Delegates or no delegates, whether a properly constituted general meeting or not, there was a good assemblage of members and friends in the evening when the President assumed the chair and read a telegram which had arrived in acknowledgement of that sent to the King.

The President-Elect.—Mr. ANDREW CLARK then stated that at the morning council meeting it had been resolved to recommend that an invitation to Swansea for 1903 be accepted and Dr. T. D. Griffiths nominated President-elect.

The recommendations were unanimously accepted and Dr. Griffiths in a modest speech promised that his own shortcomings would be compensated by the co-operation of his colleagues and the warm Celtic welcome they would meet in the Principality.

Mr. F. FOWKE, the secretary, after thirty years' service, had felt bound to resign and was elected an honorary member.

The President then introduced Sir Thomas Barlow, who he said must be known to all by name, but he would refer to one thing—that Sir Thomas was a native of that district (applause). They had to congratulate themselves that one of themselves had raised himself to the highest pinnacle of the medical profession. He then called on Sir T. Barlow to deliver the

Address in Medicine.—Sir THOMAS BARLOW was received with great cheering as he stepped forth to deliver his address. He began with a reference to the address of twenty-five years before delivered by Sir William Roberts, the recollection of which, he said, gave humbling reflections to one who had to take up the parable where Roberts left it. In drawing attention to some recent advances he offered this thesis: "The advances in the treatment of disease have been real and satisfactory in proportion as they have been harmonious with the complete knowledge of the natural history of disease." He would not say that good treatment owed its origin entirely to pathology—far from that; it had often antedated pathology—but in proportion as pathology had become complete it had rationalized good treatment and refined it, separating, so to speak, the ephemeral from the permanent, the accidental from the essential, as well as the harmful from the beneficient. Moreover in these last days in not a few instances the true pathology had laid down new therapeutic lines which had been justified by experience

The speaker took up first diptheria and the great changes that had taken place in the matter of hygienic and medicinal treatment as well as in the views regarding the etiology and diagnosis of this disease. The old theories of exposure to cold and sewer-gas poisoning have given way to that of infection by bacteria, and especially of the spread of the disease by personal contagion, the dangerous cases in this regard being the mild and unrecognized ones. The treatment has been revolutionized by the introduction of antitoxin, and bacteriology has made of the diagnosis of the disease an exact science.

Dr. Barlow then spoke of tetanus and its specific treatment, and observed that the tenacity of the combination between the toxin and the nervous tissues which was shadowed forth in diphteria was in tetanus the dominant factor. It woud appear to be the tissues of the central nervous system for which the toxin had a special affinity, and later investigations pointed to the necessity of subdural injections into the cerebral substance itself, as well as into the cellular tissue, and to the employment of far larger doses of the antitoxin than the first immunization experiments suggested.

After referring to other examples of specific medication in the treatment or prevention of rabies, smallpox, blood-poisoning and other infectious diseases, he discussed at some length the treatment of tuberculosis in the light of modern discoveries. The teaching of pathology, he said, is that the fortifying of the general resistance of the individual is the most important indication of all. Real true advance always tends to simplification, and the great fundamental therapeutic remedies are the employment of fresh air, sunshine, of good food, and of regulated exercises. This, surely, is the inwardness of what has been called the sanatorium treatment. "Let us gracefully recognize," he continued, "what Brehmer and Dettweiler and Trudeau and Walther have taught us; but we should remember that sixty years ago an Englishman—a village general practitioner, George Bodington, of Sutton Coldfield—taught, both by precept and by the results of actual experience, what were the proper methods of treating phthisis. The measures upon which he relied were that the patient should live most of the day in the cool open air; that his rooms should be thoroughy ventilated, and in temperature not varying greatly from that of the outer air, that daily driving or riding, and, as soon as possible, walking should be enjoined; that a generous diet should be given, and that all this should be carried out under the assiduous daily and even hourly supervision of a doctor living under the same roof or close by." A very practical suggestion of the orator was that physicians should speak more guardedly about the cure of consumption and insist rather upon its arrest. In that way they would impress upon the individual, as well as upon the enlightened community, the vital necessity of a prolonged after-care of the tuberculous subject.

Other points touched upon by the speaker were malaria, Malta fever, rheumatism, and organotherapy, the latter as exemplified chiefly in the striking influence of thyroid extract upon the course of myxœdema. In the light of these wonderful advances in the near past and the present, the outlook for the future was bright indeed.

Sir **William Broadbent**, in proposing a vote of thanks for the address, declared that Sir T. Barlow had set forth the importance of scientific investigation and expounded the whole of the considerations bearing on diphtheria and antitoxin, as he, for one, had never heard them set forth and expounded before.

The resolution was seconded by Dr. **Markham Skerritt**, and carried unanimously. Sir Thomas briefly replied, thanking the audience for their patient hearing of his long address.

Thereupon followed a general exodus to the open-air fête and reception in the beautiful Whitworth Park, brightly lit up by festoons of colored lights among the trees, and the band playing in the kiosk. The Art Gallery was also thrown open for those who preferred it, and there, too, was music.

Thursday, July 31—Third Day.

Address in Obstetrics.—There was another great gathering of members to hear this address, which was delivered by Professor **William Japp Sinclair**, who took for his subject, "Carcinoma in Women, Chiefly in Its Clinical Aspects." He began with a brief consideration of the pathology, old and new, of cancer, from which he drew the conclusion that practically nothing had been accomplished in solving the problem of the causation of the disease. As to the results of the surgical treatment of cancer of the uterus, the speaker was not quite so pessimistic. He said that in recent years there had been a wave of mental depression passing over the gynecological world on account of the unfavorable remote results of vaginal hysterectomy for cancer. He quoted some very gloomy views expressed at recent gynecological congresses in America and Germany, but said that, so far from the pessimistic view being the true one, the results obtained by many of the best-known operators continued to improve and to give the greatest encouragement to continued efforts in the future. They were obtaining better immediate results, and the number of "cures" increased—that is, the percentage of immunity for at least five years after operation was becoming greater. The percentage of cases operable when first seen had also increased, because the patients came earlier for treatment, and improvements in technique had extended the indications. The proof of all this lay in the statistics of carefully reported work done under circumstances in which the sources of error were reduced to the minimum.

One of the evil results of the depression arising from the recognition of the unfavorable remote results of vaginal hysterectomy had been a rush, especially in Germany, to the extreme verge of the practical in dissecting out not only the internal sexual organs, but the whole of the lymphatics and cellular tissue of the pelvis. This had been declared to be justified by the belief that better remote results would be obtained than by vaginal hysterectomy. From a careful and laborious attempt to keep up with the record of proceedings, the speaker said he had no hesitation in asserting that a large portion of the extended radical abdominal hysterectomies for cancer were homicidal vivisections, which nothing hitherto advanced in their support appeared to palliate, much less to justify. Dr. Sinclair did not believe that cancer of the uterus was on the increase, but rather that the frequency of its recurrence was diminishing. This, however, should not lead to any relaxation in the efforts being made to discover the cause of cancer and improve the technique of operations for its removal. Cancer, he said, was infectious to the individual already suffering from the disease, but to no other, and the remedy, therefore, lay in early surgical interference. In concluding, he said that, running through all his address, had been an effort to attract attention to the dignity and the effectiveness of exact scientific clinical methods of observation. To attain his object, it seemed necessary to call specific attention to the futility of much of the labors of the past undertaken to establish the etiology and true pathology of cancer. All honest and enlightened human effort should be welcomed, and he depreciated none. But chiefly was his hope fixed on the fact that in such research as he had been suggesting every member of the medical profession engaged in general practice could co-operate in genuinely scientific work with those whose daily occupation was of a special character. The work of both sets of workers would be complementary. The specialists should have more time, as a rule, to devote to such work, and naturally they had the particular disease more in their minds. The medical practitioner knew most about the history and environment of the individual patient, and could obtain relevant information from which the hospital physician was excluded. His earnest hope and desire was that some of the younger men, with more energy, better opportunities, starting on a higher level of knowledge, would professedly take up this great enterprise and see whether by calm, industrious, and enlightened clinical observation, alone or collectively, they could discover the cause and the remedy for this mysterious and dreadful malady.

Afterward, there was another garden party, with a pastoral play. The annual dinner followed, and that was succeeded by the ladies' reception and variety entertainment in the theatre.

Friday, August 1—Fourth Day.

The Sections resumed in the morning, but the rest of the day was given up to picnics, garden parties, games, and other entertainments. In the evening the Lord Mayor held a reception and conversazione in the Town Hall, and this was followed by a ball in Platt Hall Park, given by the President and Local Committee. Many members left this day, and more on Saturday, which was, as usual, set apart for excursions.

SECTION OF MEDICINE.

Wednesday, July 30—First Day.

A Discussion on Dilatation of the Stomach.—This was opened by Professor **Clifford Allbutt**, who proposed that the discussion should be limited to the atonic or non-obstructive dilatations of the stomach, as the obstrucive dilatations were, comparatively speaking, well understood. Atony and atonic dilatation had not received the attention they deserved; atonic dilatation being, indeed, neglected by some physicians, and by a few even denied. The stomach was supported more firmly at the cardiac than at the pyloric end; and in estimating atonic dilatation the area of the cardiac portion was to be carefully observed The stomach, as a whole, might drop into the mid-abdomen or hypogastrium, and this independently of more general enteroptosis. Gastroptosis was not necessarily attended with dilatation. The relation of gastritis to dilatation of the stomach was referred to. Excess of hydrochloric acid was not necessarily a consequence of gastritis; it might rather be the cause of it. Relaxation of the stomach due primarily to muscular failure, might depend upon toxic causes or mere atony. Such gastric distention, advancing to dilatation, not uncommonly retarded convalescence from such diseases as typhoid fever and rheumatic fever. When the condition followed slow digestion with fermentation, anæmia, or mere inanition, the muscular failure was primary. Spasm of the pylorous might cause dilatation of the stomach. That the nervous system might be concerned in paresis of the stomach seemed likely enough; not only continuously depressing causes might act in this way, but sudden and grave mental shock might be quickly followed by considerable atonic dilatation of the organ. Alcohol, in so far as it might be a cause of dilatation, might act directly as a poison to the muscular fiber, or indirectly by extensions of inflammation outward. Atonic dilatation of the stomach was no rare consequence of exhaustion from muscular or mental exertion.

The symptoms of atonic dilatation were often indefinite if not misleading. There might be little or no loss of appetite or dyspepsia. Vertigo, sleeplessness, heaviness, lassitude, fatigue, and mental depression, might divert attention to the nervous system. Flatulence was rarely absent

Among the physical signs referred to was gastroptosis, which was not difficult to detect in thin persons (in well nourished persons it seemed never to occur); peristalsis was rarely visible; the signs of distension were chiefly to the left of the middle line, and under the lower ribs. The area of resonance might rise to the fifth or fourth rib, and extend to the posterior axillary line. Such a stomach often accompanied disease of the heart, and played a large part in the patient's distress. Physical examination must be made at various periods of digestion, and when the stomach ought to be empty. In health the stomach after a meal should contract upon its contents, when an area of dulness rather than of resonance would become apparent Even in acute indigestion there was a considerable grip of these contents, a grip often attended with stomach-ache, but in atony, with or without static dilatation, an area of resonance at the cardiac end would be found almost immediately after a meal; even four or five hours after a meal the vault remained high, and behaving capriciously under gaseous influences, at no time did it contract in regular periods. The pyloric moiety, in its turn, unable to withstand the gravitation of its contents, increased from its comparatively small transverse diameter until the stomach, as a whole, might assume a uniform thick sausage-shape. Strangulation by sharp flexure of the pyloro-duodenal portion might occur. Dilated colon might be mistaken for a dilated stomach, but in the majority of instances by percussion, the two organs may be distinguished. In difficult cases syphonage or insufflation might help. The tuning-fork, ausculto-percussion, and coin-tapping, in the speaker's experience, added little or nothing to what careful percussion could tell us. In atonic dilatation there was rarely the succussion splash of obstructive dilatation. In atonic dilatation sarcinæ and torulæ were not usually found, and lactic acid but rarely, and in small quantity. In atonic dilatation the return of water introduced into the stomach was very feeble, or was, perhaps, obtained only by expression or syphonage The treatment of atonic dilatation must largely depend upon the causation of the individual cases; particular symptoms would often indicate the means of their own palliation. Vertigo and lassitude after meals often depended upon distention of the stomach, and might be relieved by a careful regulation of diet and restriction of fluid at meals to the lowest quantity. In sleepless cases, besides these measures, hydrotherapy was often useful. In heart disease, after much disappointment in the use of specific remedies, the cure or relief of an atonic dilatation of the stomach might be attended with remarkably good effects. Papain had proved a very useful aid in digestion In some emaciated persons the full Weir-Mitchell system might be necessary, and especially in gastroptosis; in all a long rest and change of air were of the first importance.

Dr. **Noel Bardswell** described the conclusions arrived at as a result of routine examination of stomachs in all cases under his care for the treatment of pulmonary tuberculosis. In practically all cases of early disease, whether slight or fairly acute, of say from three to six months' duration, the stomach was found to be normal in size, the only exceptions being in those who gave a history of prolonged antecedent dyspepsia. The importance of examining stomachs in such cases before administering ordinary sanatorium diets was great. Although the stomach of early cases would usually stand the administration of very large diets, there was a tendency for prolonged hyperfeeding to cause dilatation, and this without symptoms of dyspepsia. Clinical experience suggested that, other things being equal, the longer such patients were kept at absolute rest (and such treatment usually implied the existence of fever) the greater the tendency to atony and dilatation. The prolonged administration of high ordinary diets to consumptives after the development of symptoms characteristic of atonic dyspepsia was unnecessary and unjustifiable in view of the serious prognosis which must be given when active pulmonary tuberculosis was associated with dilatation of the stomach. During the past two years there had been under care eight patients (originally of the acute type of pulmonary tuberculosis which we are now considering) who had previously been some six months in sanatoria where excessive feeding was practised. In five of these patients definite enlargement of the stomach was found. In three of these the dyspeptic symptoms cleared up under physiological dieting, and in two the stomachs largely recovered their tone. On the strength of the experience gained when dealing with cases with symptoms of atonic dyspepsia, the diet was amended by reducing its bulk without diminishing its nutritive value. The following was a sample of such a diet: Milk, $2\frac{1}{2}$ pints; eggs, 2; fish and meat, $5\frac{1}{2}$ oz.; butter, 2 oz.; milk pudding, 7 oz.; arrowroot or cornflour, 4 oz.; plasmon, $1\frac{1}{2}$ oz. The weight of this diet was 74 ounces as against 98 ounces of the former, or a reduction of 25 per cent., and its nutritive value was a trifle higher, viz., 147 of proteid compared with 137, the fats and carbohydrates being the same in both. Chronic cases of several years standing had almost invariably pronounced anorexia and dyspepsia, and about 50 per cent. had some degree of stomach dilatation. In spite, however, of their frequently starting treatment thus handicapped, their stomachs appeared to stand sanatorium treatment better than one would expect.

Sir William Broadbent emphasized the frequency of nervous causes of gastric dilatation, as from fatigue, and the wear and tear of city and commercial life. Dilatation of the stomach was often the determining cause of the fatal termination in acute disease, as in rheumatism and pneumonia. In the case of weakly women, the less they ate the worse often they digested. The symptoms of dyspepsia were usually conspicuous by their absence in dilatation. Dilatation of the stomach might increase to an enormous extent, even from the hypochondrium to the pubes, and turned back again to the hypochondrium—and that without any mechanical obstruction. Other symptoms of importance were pain simulating angina, occurring even during repose; extreme palpitation and vertigo, which were probably the direct result of mechanical pressure, as the eructation of gas ended the distress. Tetany was an occasional concomitant of dilatation of the stomach. In one case, after the tetany had disappeared, it returned after severe shock. The mechanical effects were modified when the stomach dropped down. Other symptoms were probably the result of the absorption of the products of fermentation. In one case referred to, the development of Hodgkin's disease seemed to be related to dilatation of the stomach; lavage of the stomach was followed by a rapid diminution of the glands not only in the abdomen, but everywhere; in a second case improvement followed lavage after three weeks' treatment. The diagnosis might be either extremely easy or very difficult. It was common to find the stomach resonance extending transversely to the ensiform cartilage. The echo of the heart sound was often of value, as heard with the stethoscope, in defining the limits of the dilatation. Gravitation of the stomach contents was often of value in determining the lower limit of the stomach. Hemorrhage from a dilated stomach, pure and simple, was sometimes met with. Measures for disinfecting the stomach were alluded to. The use of the tube was especially indicated last thing at night.

Professor Musser divided cases of dilatation into those with ptosis, and those without. In the ptosis cases some patients had hyperchlorhydria, and the affection was mainly neurotic or toxic in origin; and in some cases disorders of the reproductive system were a causal factor. Among toxic causes were tea, tobacco, and the poisons of septic diseases. The physical health in such cases might be excellent. In other cases—called the neuro-cardiovascular type—there was weak heart's action, with polyuria and the presence of tube casts. In the cases with ptosis there might be no subjective symptoms. In some cases there was marked neurasthenia, the cause of which was obscure. Inflation by means of the tube alone was sometimes of much value, care being taken not to dilate the organ too much, and auscultation being practised simultaneously. In regard to profusion, eighteen months or two years were usually required for a distinct improvement. Except in extreme cases of dilatation, lavage was better not employed; and in any case it should be practised by the physician alone.

Dr. T. D. Savill thought one of the commonest causes of dilatation of the stomach was a septic condition of the mouth, as in pyorrhœa alveolaris. The relation of tetany to dilatation of the stomach depended probably on absorption of toxic products. Splashing and the percussion methods with gaseous dilatation were to be depended on—a draught of aerated mineral water might be employed for the purpose. In some cases the galvanic current gave excellent results. Diet alone was efficacious in some cases alone, particularly the so-called Salisbury diet. Change of diet was of importance, and fermentation by the Salisbury method was largely obviated. Drugs having a special action on carbohydrates were indicated.

Dr. Harry Campbell described the essential agency of the symptoms of gastric dilatation, namely, gaseous pressure, but the presence of solids and liquid had an influence apart from their own weight by diminishing the space available for gas. The aim in treatment should be to give a diet as non-flatulent as possible and for this purpose, perhaps, none was better than the Salisbury diet. All liquid should be given before meals. In regard to distension, it should be remembered that the amount of gas to be obtained from an effervescent mixture could be estimated. The lower limit of the stomach could usually be detected by ordinary percussion. The splashing sound occurred in normal persons. Depression of spirits was doubtless in many cases due to the absorption of toxins, but the mechanical pressure of a dilated stomach seemed to have a direct influence.

Dr. Alfred Parsons considered that it was of importance to assure patients that their disease was by no means incurable. The hypochloric acid test was sometimes of great service. The absence of the acid was of importance, but its presence contraindicated malignant disease. Succussion was valuable in some cases if obtained from four to six hours after meals. Allusion was made to a fatal case of gastric tetany in which operation seemed indicated, but could not be performed. In another case death occurred in eight hours after a gastroenterostomy.

Dr. Mantle referred to the vascular and nervous supply of the stomach and the relation of worry or shock to them in producing dilatation. Disturbed innervation led to diminished motility—eventually to dilatation. The condition of dilatation was often associated with cold extremitities and other evidence of vasomotor weakness. In treatment rest was of prime importance. The drinking of large quantities of water, containing a disinfectant, followed by emesis, could for private patients be used instead of lavage.

Dr. William Colwell thought the shape of the stomach, resonance, and its position varied much in different individuals and in the same person from time to time within fairly wide limits. All toxic causes might be classed together; and in exhausting conditions of any kind dilatation might occur. In some cases there was defective peristalsis with kinking of the duodenum, and in such gastroptosis was common. The hydrochloric-acid test was of great importance in distinguishing the dilatation of chronic gastric ulcer and malignant disease. The gas method in the supine position was often of service; as also was the method of introducing a small quantity of fluid by the tube before percussion.

Dr. Page May described experimental researches conducted with Professor Starling of University College Hospital on dilatation of the stomach. The gastric tone depended on local ganglia to a large extent as the contractions continued in the excised stomach. On the other hand, the central nervous system exerted a great influence on the musculature of the stomach. An India-rubber bag containing air and introduced into the stomach was used to give tracings. Stimulation of the peripheral end of the divided vagus first arrested movement and was then followed by an increase. The inhibitory effect was much more marked in the cardiac than in the pyloric end. Stimulation of the splanchnic nerve increasing the blood pressure gave no effect on the musculature of the stomach.

Dr. Haddon alluded to the effect of too frequent meals in producing dilatation of the stomach, and to the influence of maintaining a good action of the skin in relieving symptoms.

Professor Allbutt, in reply, said he thought tetany was rare except in cases of dilatation from mechanical obstruction. He had not found much dilatation of the stomach traceable to tobacco. Gaseous pressure depended to a great extent on the temperature of the gases. There was much difference between a big and strong stomach and a dilated stomach.

The Dietetic Treatment of Chronic Granular Kidney.—Professor Carl von Noorden, of Frankfort-on-the-Main, then read this paper, giving a report on his investigations on the excretory power of the diseased kidneys. It was one of the principal aims of the dietetic treatment as far as possible to keep from patients all those articles of food the metabolic products of which were only with difficulty and imperfectly excreted by the diseased kidneys. When such products of metabolism were brought in contact with the kidneys they constituted a strong stimulus for that organ; the damaging element lay in the disproportion between the stimulus on the one hand and the excretory power on the other. The speaker had studied the elimination of the natural products of the metabolism under different points of view. After having quoted the relative facility of elimination of these substances in acute nephritis, he described the eliminatory functions of the chronic granular kidney.

As far as the material at hand permitted the following questions could be discussed:

(1) How much albuminoid substances was to be allowed in granular kidney? He had pointed out how much nitrogen was excreted on the average by patients who had for some time been enjoying as good health as could be hoped for in the course of chronic nephritis. This was found to be on the average, in men, between 13 and 16 grams, and in women, between 11 and 14 grams, daily, calculated on the basis of 70 kilo weight of the body. This corresponded with 92-112 grains of albuminoid food in men, and of 80-100 grams in women. On the other hand, it was pointed out, when the albuminoid substances were slowly increased the patients usually secreted with the greatest ease quantities of nitrogen less than 14 grams (for 70 kg. weight), but as soon as the ingestion of albumin was increased, so that considerably more than 14-15 grams nitrogen daily had to be excreted by the kidneys, the elimination becomes irregular and uncertain. The empirical numbers and those ascertained experimentally corresponded perfectly.

(2) Was the quality of the albumin of any influence? Uric acid was not always readily eliminated. Therefore the patients were not allowed to eat substances which were rich in nuclein, glandular tissues, as sweetbread, liver, kidney; further exhaustive experiments had been made regarding the secretory power under the ingestion of corresponding quantities of the albumins of meat, fish, eggs, milk and vegetables. The diseased kidneys made no distinction between these various albumins. Other experiments had shown beyond doubt, that it was of absolutely no consequence for the eliminatory functions of the kidneys whether one gave red or white meat to the patient. In regard to these facts, the patient could be allowed much more freedom and variety in food than usually was the case, and their appetite could be kept up.

(3) Should the patient drink much or little? It seemed advisable not to allow more than three pints of fluid daily in cases of granular kidney, as by inundating the vascular system with water they correspondingly increased the work of the heart, and did it permanent damage. Restriction of the fluid spared the heart, whose weakness in many cases of granular kidney was more dangerous than the alterations in the kidney itself. Investigations on metabolism show that the diseased kidneys worked and excreted pretty well as long as the daily quantity of liquid is not reduced below three pints daily, not taking into account the water contained in the solid and semi-solid articles of diet.

(4) How much should the daily total quantity of food be? On it depended in the first instance the amount of fat produced in the body. Stoutness was a bad complication of Bright's disease; either was a source of danger to the heart, but their combination more than doubled the risk to life. The rule which could be derived from this point of view, and the general clinical experience was to feed patients suffering from granular kidneys with plenty of strengthening food, but under no circumstances to overfeed them. Whenever the weight must be reduced this reduction must be effected in the most cautious manner. The usual cures at Carlsbad and Maricubad were entirely unsuitable in cases of granular kidney. Such patients did much better under immediate medical supervision in hospitals and sanatoria.

Sir W. Mitchell Banks then read a paper describing a successful case of gastroplication for dilated stomach in which a fatal result was threatening. Pain and vomiting rapidly followed the operation, and two years later the man had had no relapse and he had gained weight.

Thursday, July 31—Second Day.

Differential Diagnosis of Functional and Organic Paralysis.—Dr. Buzzard opened the discussion on this topic, remarking that the expression "functional" as employed in this country was scarcely ever met with in the writings of continental authorities, where the cases of that class were always called "hysterical." Without attempting to define the word he thought that, for the purposes of the discussion, it would be convenient to consider it as applied to cases of paralysis which simulated more or less closely those arising from structural alterations, of recognized character, of the nervous system, without being dependent upon any that the most advanced means of investigation enable us to distinguish. He also thought that the term should be limited to cases of paralysis of a kind which it would be possible for at least some healthy persons to produce by voluntary simulation. This was not to imply that they are so produced (he entertained no doubt about the reality of the disorder), but in order to exclude from the category such examples as paralysis confined to the district of a single nerve-root or trunk of a mixed nerve. Functional paralysis could sometimes (though by no means always) be removed rapidly or suddenly as a result of persuasion or physical or moral shock. He enumerated many symptoms which were conclusive as to the existence of organic disease, and thought that, on the other hand there were probably none which, unsupported, could be relied upon to establish a diagnosis of functional paralysis. Functional hemiplegia was rarely preceded by anything resembling apoplectic seizure; it was most commonly of somewhat gradual onset, and was principally differentiated by its failure to present that gradual passage from flaccidity to contracture which was characteristic of the organic form. It was prone to be associated with an amount of anæsthesia far exceeding that usually observed in organic hemiplegia, except of that form in which there is lesion of the sensory tract in the internal capsule. The points of difference between organic and functional hemianæsthesia were considered. Reference was made to the characteristic hysterical gait. This had been well described by Todd, to whom we owe also the observation that hysterical hemiplegia rarely if ever attacked the face. Apparent exceptions to this experience were described. Attention was drawn to Babinski's "flexion combinée de la cuisse et du tronc" as an important test. In organic hemiplegia an effort to sit up in bed without the aid of the arms causes the heel of the affected side to be lifted, which does not happen in the functional form.

Although a process of slow and gradual contracture was not prone to occur in the course of functional hemiplegia, a strong contracture (without previous flaccidity) might take place and present a very strong prima facie resemblance to the result of an organic lesion. In such circumstances a point which the speaker had described many years ago was useful for differential diagnosis. In true hemiplegic contracture of long standing he had pointed out, the whole arm cannot be passively extended at one movement, but in the functional form the arm, hand, and fingers can all, by an effort, be brought into one plane. He did not think the inequality of the deep reflexes on the two sides could be absolutely relied upon to prove that the hemiplegia was of organic origin, although it was without doubt a very strong indication in that direction; and the same obtained with regard to ankle clonus, which was sometimes, though very rarely, in the functional form indistinguishable from that characterizing organic lesion. Dr. Buzzard said that many years' continuous experience had entirely confirmed an observation published by him some twenty years ago as to the absence or difficulty in eliciting plantar reflex in functional paralysis, and he thought the symptom was of great service as a negative sign in differentiating functional from organic paralysis. The "toe phenomenon" described by Babinski in 1896, was probably of still more importance, since it gave positive evidence of organic disturbance. Monoplegia of functional origin was then discussed, and it was shown that although in many cases the character of the affection could be conclusively demonstrated, its differentiation might sometimes present insurmountable difficulty.

Paraplegia, he thought, rarely presented any serious difficulty, especially because of the aid to diagnosis afforded by the Babinski toe phenomenon and his own symptoms of absent plantar reflex. Some remarks were made on the electrical condition sometimes observed in muscles in cases of functional paralysis tending to misapprehension, and the various signs indicating functional paraplegia were described.

Some remarks on the comparatviely moderate and often transitory paralysis of a limb or limbs in insular sclerosis concluded the address. Attention was drawn to the extreme frequency with which this was erroneously regarded as of functional character, and how much deplorable injustice was thereby inflicted on the numerous sufferers from this disease. He combated the idea held by some that these attacks of localized paralysis were at first hysterical and eventuated in organic change, and expressed the opinion that it was the attack of structural disease in the central nervous system which incidentally caused also hysterical symptoms. Not only physical shock but the shock of structural disease was prone to induce along with its immediately resulting symptoms others of a functional and often transitory character. In conclusion he urged that the medical student should receive accurate instruction and study of the Babinski toe phenomenon as a most important means of differentiating organic from functional paralysis.

Sir **William Broadbent** referred to the difficulty of distinguishing the early paralysis of insular sclerosis from a purely functional paralysis and the importance of Babinski's phenomenon in this relation. A series of four cases of functional paraplegia, due to suggestion by the same person were referred to. Extraordinary vascular changes were seen in functional paralysis, such as absolute increase in volume of the limb and extraordinary changes in the color of the limbs. After some congratulatory observations by Sir **James Grant** of Canada, Dr. **E. F. Trevelyan** of Leeds recounted some cases of functional paralysis having a bearing on diagnosis; including functional aphonia and hemiplegia.

Dr. **Judson Bury** divided cases of paralysis into malingering, functional, and organic. There seemed to be no reliable test, unless it were Babinski's test, which could be used to separate organic from functional paralysis. Even Babinski's test was probably not quite reliable. Recovery from paralysis could not be taken as a differentiating feature. It was necessary first to decide what part of the nervous system was affected, and then whether the change was vascular or cell-change, or other. Functional as a term was objectionable. All early changes of organic disease were probably identical with the changes of so-called functional disease.

Dr. **E. S. Reynolds** considered that nothing was more unfair to the patient than that some organic disease should be ascribed to functional disease. Probably the most difficult cases were those of compensation for railway injuries. Reference was made to cases of disseminated sclerosis, brain tumor, and general paralysis, in which handwriting was a distinctive feature and guide. Ankle clonus was probably a valuable evidence of organic disease, confirmed by Babinski's sign when present. Incontinence of urine, formerly supposed to be confined to organic disease, occurred in functional paralysis. The gait should always be observed with the patient's feet uncovered. In one case a scraping gait was conjoined to flexion of the toes. If the patient flexed his head against resistance the platysma contracted on both sides in functional paralysis, but only on the unparalyzed side in organic hemiplegia.

Dr. **T. D. Savill** referred to tne fact that anæsthesia was present in almost all cases of functional paralysis, being mostly hemianæsthesia and more frequently on the left side and often conjoined with implication of the special senses and contraction of the visual fields. The scattered nature of the signs of functional disease was characteristic. The variability of the symptoms in functional disease was remarkable; also the tendency to sudden and absolute disappearance of the clinical phenomena; and the ocurrence of vasomotor phenomena or flushings, and localized erythemata. These features suggested that the pathological changes underlying them were vascular or, at any rate, associated with the sympathetic system

Dr. **Harry Campbell** considered a functional paralysis depended on an undiscoverable lesion by ordinary powers of the microscope, but such lesion in the future might be discoverable. Such conditions as myasthenia, Grave's, Landry's paralysis, paralyses in Grave's disease, also toxæmic paralyses in their early stages, showed the difficulty of saying where functional disease ended and organic disease began. In case of diphtheria or diabetes there was often loss of knee-jerk without paralysis, and this was often considered as a certain indication of organic disease. Ankle clonus and Babinski's sign, when unmistakable, were evidence of organic disease. Cerebral vomiting and diplopia were no evidence of organic disease. Fixed pupil had been recorded in functional disease.

Dr. **F. W. Mott** referred to a test he had recently introduced—the cholin test—for which he invited attention and a trial. An excess of cholin in the blood indicated a considerable degeneration of the nervous system. The physiological test was the most reliable, but was not convenient. The clinical test was easy to perform. There was a proportional relation between the amount of cholin in the blood and the degree of nerve degeneration found after death. Small quantities of cholin were probably present normally in the blood as a result of healthy nerve metabolism, and hence the test was a comparative test. About 5 or 10 c.c. of blood were abstracted for the test, preferably from the vein. The difficulty in the test being to get rid of the potash salt, the blood was received into successive quantities of absolute alcohol, which removed them, and after the addition of bichloride of platinum crystals separated out, which were purified with alcohol and examined under the microscope. The injection of cholin into the vessels of an animal causes a fall in blood pressure.

Dr. **David Drummond** emphasized the importance of certain signs which were almost unequivocal in differentiating functional from organic disease, particularly the Babinski's sign. There were few, if any, signs which always gave a positive result, but their practical value was great notwithstanding. Of such were paralysis of the face and relaxation of the sphincters.

Dr. **J. M. MacCormac** considered that paralysis of external ocular muscles, when not due to disease in the orbit, indicated organic disease, so also did the Argyll Robertson pupil. Paralysis of the palate and well-marked and persistent hemianopsia, paralysis of the muscles, reaction of degeneration in wasted muscles, and other evidence of organic disease, were referred to. Functional disease could not be excluded until a sufficient interval had elapsed, to make sure that it would not develop into the organic.

Dr. **Purves Stewart** gave a lantern demonstration illustrating characteristic differences in the attitude and gait in functional and organic palsies, respectively.

Dr. **Dreschfeld** (the President) alluded to the presence of tremor in functional disease, and to the presence of Babinski's phenomenon in non-nervous diseases. The combination of extension of the big toe and flexion of the other toes was a certain sign of organic disease.

Dr. **Buzzard**, in reply, acknowledged that Babinski's sign did not always succeed, but observation of three years had established its great value.

Infantalism and Senilism. Dr. **Gilford Hastings** then read a paper with this title and showed cases and photographs. Infantilism might be proportional, in which case it might be considered normal, but usually it was not so and was associated with other disease and, therefore, abnormal. It was commonly connected with imperfect ction of important organs as the thyroid Ateliosis was a condition of dwarfism with abrupt onset and absence of perceptible cause, infantilism, defective development of reproductive system, unimpaired intelligence, but in one case with microcephalus. Ateliosis might be described as a sort of stereotyped childhood. Ateliosis might commence at any time, if after childhood the characteristic features were not manifested. Senilism represented a premature maturity or old age, which might be normal or morbid, indicated by premature development. Several varieties of the condition were described with illustrative case

The paper was discussed by the President, Dr. McWalter; and Dr. Harry Campbell and Dr. Hastings replied.

Friday, August 1—Third Day.

Demonstrations of Apparatus for Clinical Research.—The greater part of the work of the Section on the third day of its meeting consisted in demonstrations of clinical apparatus and methods of research.

Dr. James MacKenzie demonstrated his new and simple form of clinical polygraph and phlebograph, by which simultaneous tracings from the heart arteries, veins, enlarged liver, and other pulsating surfaces could be taken and synchronised. A system of tambour, lever, and india rubber tubes connected with a metal cap fitting on the pulsating surface was attached to a Dudgeon's sphygmograph as a recording apparatus. The President, Dr. Dreschfeld, said he had had the apparatus in use in his ward at the Royal Manchester Infirmary and had found it of much practical utility.

Dr. George Herschell demonstrated the hæmoglobin scale of Dr. Tallquist of Stockholm, and also showed an apparatus for safely inflating the stomach in order to facilitate the determination of its boundaries. This consisted of a force pump in the erect position, the piston of which would fall by its own weight so as to drive from a connected flash a paroleine spray through one limb of a double stomach tube introduced into the stomach. Through the other tube the spray escaped when the stomach was fully dilated.

Dr. Walker Hall showed his Purinometer for the clinical estimation of purin bodies in the urine, and made a communication on the general subject which was discussed by Dr A Luff and Professor Dixon Mann.

Bacteriology of Arthritis.—Drs. F. J. Poynton and Alexander Paine then gave a communication and lantern demonstration, describing their observations on the bacterial origin of certain forms of arthritis. Their observations were chiefly confined to the rheumatic, rheumatoid, and septic types of arthritis, and commenced with an allusion to the isolation of a diplococcus from the throat of a man suffering from rheumatic angina, and the reproduction of rheumatic manifestations, including polyarthritis by intravenous inoculation of this diplococcus into rabbits. The researches of Fritz-Meyer and Loffler were commented upon. As a result of a clinical, pathological, and experimental study of rheumatic arthritis, the authors concluded: (1) That the primary seat of deposit of the microorganisms was in the synovial tissues; (2) That the endothelium served as a barrier to their escape into the joint cavity; (3) That there was active phagocytosis both in the synovial tissues, and also in the articular exudations, when the microorganisms escaped the endothelial barrier and reached the cavity of the joint. It was highly important to recognize that the escape of the microorganisms into the joint cavities was a vital and not a passive process, and since rheumatic arthritis was such a transitory manifestation, it was to be expected that the cultures would be often negative. In severe cases the diplococci were present in the exudation, clinging to the fibrinous strands, and the endothelium was in such cases more or less destroyed.

In chronic rheumatic arthritis of long duration there occurred a perivascular fibrosis around the small blood vessels. The contraction of this fibrous tissue diminished the lumen of these blood vessels, and thus impaired the nutrition of the synovial tissues. The speakers believed this perivascular fibrosis explained to some extent the intractable nature of these forms of arthritis, and their slow reaction to treatment.

A very interesting type of arthritis had been especially described by Dr. G. F. Still as occurring in childhood It was characterized by much periarticular thickening. The lymphatic gland and spleen were enlarged, and the pericardium might be adherent. There was doubt as to how such cases should be classified, whether as rheumatic, rheumatoid, or as a special disease One such case under the care of Dr. Parkes Weber they had investigated during life with negative results, but there was, in spite of that, little doubt of their bacterial origin.

The observations upon rheumatoid arthritis were limited to four particular points: (1) Whether or not there was a specific disease which could be called rheumatoid arthritis; (2) The production of rheumatoid arthritis by intravenous inoculation of a diplococcus; (3) The relation of the nervous to the arthritic phenomena; (4) The relation of rheumatic fever to rheumatoid arthritis.

Amongst all the uncertainty that surrounded the study of rheumatoid arthritis, it seemed clear that many different infections might produce this condition. Whether there was in addition to these a special disease still required elucidation. It was also undoubted that microorganisms injected into the blood stream might produce a rheumatoid arthritis, as the authors had demonstrated in January of this year. Whether the nervous phenomena and arthritis were the result of some peculiar poisons acting upon both these tissues, or whether the arthritis was in reality neurotrophic, were questions which had to be approached at present with an unbiassed mind, and they thought the former view would prove to be the correct one. Rheumatoid arthritis following repeated attacks of rheumatic arthritis, they thought, might be the result of an intensified local virulence of the rheumatic infection, and not due to a secondary infection. This seemed probable to them because they had found that both simple and malignant endocarditis might result from inoculation with the diplococcus of rheumatic fever, and rheumatoid arthritis in rheumatic subjects appeared to them as the parallel in the joints to malignant endocarditis in the heart.

Upon two occasions they had isolated the pneumococcus from suppurative arthritis complicating pneumonia, which gave additional support to the writings of Leroux, and of Drs. Cave, Nathan Raw, and G. R. Murray, in England.

In the study of suppurative arthritis it had seemed best to abandon the use of the terms "pus" and "septic," for these words were often used so loosely as to convey but little real information. Examples were given to illustrate that a detailed description of the exudations in arthritis was preferable to the use of these terms "pus" and "septic." Finally, the influence that was exerted upon treatment, by the recognition of a bacterial agent in many forms of arthritis, was commented upon and exemplified by allusions to Menzer's specific rheumatic serum, the importance of investigations upon prophylaxis for the community and the individual, the necessity for a varied treatment, and the possibilities of surgical interference.

Dr. David Drummond then read a paper entitled "Some Practical Remarks on the Diagnosis of Heart Disease," dealing particularly with the diagnosis of functional murmurs, alcoholic affections of the heart, syphilis of the heart, and heart affections in renal disease.

Dr. F. M. Sandwith of Cairo communicated a paper on the earliest known physician—Sokit ne-Onkh, an Egyptian of 5,500 years ago, whose tomb had been found at Memphis.

Dr. Harry Campbell next read a paper on "Overlooked Cases of Graves' Disease," chiefly such as showed only nervousness, hand tremor, and tachycardia. It was suggested that other conditions of nervousness not clearly connected with Graves' disease might also have a pathological connection with thyroid changes, possibly with an exaggerated physiological activity of the thyroid.

Dr. CHOWRY-MUTHER described the results of the treatment of a hundred cases of phthisis by the open-air method, and Dr. A. MANTLE made a communication on vasomotor disturbances of the stomach and bowel.

With this the work of the Section was terminated.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 9, 1902:

	Cases.	Deaths.
Measles	119	8
Diphtheria and croup	167	28
Scarlet fever	92	9
Smallpox	5	2
Varicella	5	..
Tuberculosis	246	124
Typhoid fever	80	19
Cerebrospinal meningitis	..	3

A Contribution to the Study of Tropical Abscess of the Liver.—Rickman J. Godlee says that perihepatitis, usually perihepatic peritonitis, is an almost invariable accompaniment of tropical abscess. Klein's observations have shown that the direction of the flow in the lymphatics of the diaphragm is upward, and, therefore, as might have been expected, pleurisy is a very common accompaniment of tropical abscess. Rupture into the pleura is one of the most dangerous outcomes of this disease. Pleurisy may lead to serious effusion or to empyema without any rupture of the liver abscess through the diaphragm, and such an effusion may keep up the temperature after the successful evacuation of the hepatic abscess. When there is marked pleural friction, exploration of the liver should be made without delay. A patient with an imperfectly drained abscess of the lung is also exposed to abscess of the brain. Pulmonary abscess consequent on liver abscess should be opened without delay. In operating for liver abscess the best place to make the incision is in the lower axilla, as by far the greater number of abscesses occur in the right lobe, and if they be of large size they can usually be opened in this situation even if they form a projection in the epigastrium or most nearly approach the surface behind. In certain abscesses of the right lobe and in those of the left lobe the epigastric incision is the only one possible.—*Medical Press and Circular.*

Effects of Weather on Health.—A preternaturally dry air with a high temperature predisposes to the development of fevers and intestinal disorders.

A very moist atmosphere accompanied by a low temperature is likely to induce bronchial affections and rheumatism. In summer and autumn the tendency to sickness and death is chiefly connected with digestive organs.

In summer and autumn a rise of mean temperature above the average increases the number of cases of, and the mortality from, diseases of the digestive organs.

A cold and rainy summer controls the prevalence and fatality of diarrhœal diseases.

Diarrhœal diseases become epidemic when the subsoil temperature at a depth of four feet reaches 560° for the season.

The physiological effects of climate embrace the degrees of humidity, fogs, cloudiness, sunshine, force and direction of winds, purity of atmosphere, and the quality and energy of all meteorological influences.—*Ohio Sanitary Bulletin.*

Forcible Feeding.—James E. H. Sawyer gives directions for the proper use of the oro-œsophageal and the naso-œsophageal tubes. He much prefers the latter, as there seems to be less shock after its use and less likelihood of vomiting. Patients prefer it, since after the first unpleasantness of passing it through the nose there is practically no discomfort, whereas, when the oro-œsophageal tube is being passed, and as long as the mouth is kept open by a gag the attempts to swallow are very uncomfortable and even painful, and often end in retching. Great care must be taken that the tube does not pass into the larynx. It should be pulled out during expiration, so that none of the liquid still remaining in the tube shall drop into the larynx, and also because vomiting is less likely to occur during expiration than inspiration, since during the latter period the diaphragm is contracted and tends to force out the contents of the stomach.—*The Birmingham Medical Review.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 9, 1902:

SMALLPOX—UNITED STATES.		CASES.	DEATHS.

WHEN AND WHY DOES LABOR BEGIN?

By GEORGE P. SHEARS, M.D.,
NEW YORK.

CLINICAL INSTRUCTOR IN OBSTETRICS IN CORNELL UNIVERSITY MEDICAL COLLEGE.

FAMILIAR facts, or facts which should be familiar, are often forgotten. Every-day topics are frequently carelessly treated. In the search for new fields of discovery, and in the craze for bold and brilliant operations, we are prone to forget that statements which are common are not necessarily correct, and that we often know least about that which we are accustomed to regard as definitely settled.

Nowhere, perhaps, does this find better illustration than in the department of obstetrics—a subject seldom seriously studied and too often taken up only as a stepping-stone or adjunct to gynecology with its tempting field of multitudinous operative activity. Textbooks are largely repetitions one of another, old errors are perpetuated and ancient customs regarded with reverent eyes, while undue conservatism, lack of systematic study and research, and timidity in expression bar the march of progress.

Without doubt the best example of this is to be found in the history of the management of normal labor. It seems almost incredible that although the chief danger of this process is wound infection of the ordinary type, transmitted in the ordinary way, writers and teachers should have continued so long, and some of them should still continue to impress upon the mind of the innocent and receptive student, that the chief duty of the accoucheur is to make frequent vaginal examinations.

But it is not only in the management of labor that we find evidences of last-century teaching. The physiology and clinical phenomena of normal pregnancy and labor are still largely misunderstood, owing to the tendency of obstetric writers to accept the statements of others rather than to think for themselves.

For many years the "Cervixfrage," has divided obstetricians into two opposing parties. According to one school, the cervix shares but little in the growth of the pregnant uterus. According to the other, it not only shares in uterine growth, but its canal becomes unfolded for the reception of the ovum, the upper part of the canal ultimately forming what is usually known as the lower uterine segment. Those who hold this view believe that what is usually called the internal os at the end of pregnancy and what has been aptly termed the clinical internal os, the so-called ring of Müller, simply marks the limit of cervical unfolding.

For one reason or another the first view has found favor with most American writers. In most of our textbooks will be found the statement that while there occurs during pregnancy an apparent shortening of the cervix uteri this shortening is only apparent and the result of conditions calculated to deceive the inexperienced observer. It is difficult to understand why this opinion has so long held sway. Perhaps its survival is due to the unconscious effort to make the result of occasional examinations harmonize with preconceived ideas or with the dicta of authority, or to the failure to examine cases at all. It can hardly be the result of the systematic and unprejudiced examination of pregnant women.

It is safe to say that at present the weight of authority is decidedly in favor of the assumption that the lower uterine segment is formed, either in whole, or in part, in one class of cases or another, from the upper portion of the cervical canal. Some writers, indeed, while admitting that in primiparæ the cervix expands during pregnancy to form the lower uterine segment, believe that this expansion does not occur in multiparæ until the so-called premonitory stage of labor. Since, however, no definite line can be drawn between the end of pregnancy and the beginning of this premonitory stage, the distinction is of theoretical rather than practical value.

Nevertheless, a brief review of recent obstetric literature will suffice to show not only that many writers in treating of the development of the cervix during pregnancy ignore the views of a large proportion of the most earnest and scholarly workers in this field, but also that the important subject of the condition of the cervix and its canal during the latter week of pregnancy is either practically ignored or superficially or incorrectly treated.

Too often the whole subject is regarded as of academic interest only. It has, however, many practical bearings of importance, and recent experience has led the writer to believe that not the least of these is its bearing upon the diagnosis of beginning labor. That the latter is not so simple a matter as is commonly supposed, is sufficiently evidenced by the mistakes of students and beginners, and by the varying and somewhat conflicting statements of textbooks. Practiced observation and experience, it is true, often suffice even when we are not able definitely to analyze or clearly to state the reasons for our conclusions, but such observation and experience are not the property of beginners, nor can they always be relied upon. The old maxim "Whatever is worth doing at all is worth doing well," is certainly pre-eminently applicable to a scientific subject, and the question, What are the objective signs of beginning labor? is certainly worthy of a definite, and, as far as possible, a detailed and critical answer.

Subjective symptoms, as is well-known, are not infrequently unreliable. The recognition of uterine contractions is, of course, significant, but as these can be recognized at any time during the last few weeks of pregnancy they are of value, at a very early stage of labor only as corroborative evidence. What other evidence is available? It is true that in most cases there is little necessity that an early diagnosis be made and little justification for manipulations within the cervix, but now and then we meet with cases in which it is of the highest importance to determine whether the patient is in true labor; for example, cases in which, for one reason or another, it is proposed to undertake some operative procedure and cases in which it is necessary to know for purposes of diagnosis and treatment whether we have to deal with a delayed first stage.

It is self-evident that in order to make a diagnosis of beginning labor we must be prepared to answer the question—What is the condition of the cervix and its canal during the latter weeks of pregnancy? To tell whether a patient near term and suffering from the "dolores presagientes," so common in multiparæ, is in labor is sometimes a matter of no small difficulty. Indeed, by the methods usually advised, it is impossible. The ability to make the differential diagnosis is dependent upon an accurate knowledge of the conditions which obtain within the cervical canal during the last few weeks of pregnancy. And yet how much does the student find upon this subject in the average textbook?

Let us briefly recall these conditions. In most cases the cervical canal will be recognizable *as a canal*, that is, without beginning obliteration of the internal os, for a varying distance, exact measurements, of course, being hardly practicable. This persistance of the canal was doubtless the original foundation for the statement that it is not shortened, but careful examination of a series of cases will convince one that shortening does occur, that it is more marked in primiparæ than in multiparæ, and that in cases of extreme distension from any cause the degree of cervical unfolding is still greater, and sometimes, as remarked by Ohlshausen and Veit,[1] almost complete.

In a certain proportion of cases in which the head has entered the pelvic canal the familiar obliteration of the anterior lip from pressure is found, and the canal may be temporarily restored by pressing the head upward, but the statement of some writers that the restored canal is as long as it was at an earlier period of gestation cannot be admitted. The attempts to account for the plain evidence of digital examination by such theories as softening of the cervical tissues, obliquity of the canal, and so on, afford an interesting study in psychology, and are fine examples of the unconscious casuistry into which the ablest of minds may fall in the attempt to make conclusions harmonize with premises.

What such statements really mean is that the cervix is as long during pregnancy as in the unimpregnated uterus, but even this is not always true, and if it were, the obvious answer would be that the shortening is relative and not absolute. Moreover, leaving aside for the moment all the anatomical and physiological data of Bandl and his followers, it seems antecedently highly improbable that the cervix should retain its natural size during pregnancy while there is such an enormous growth in the body of the uterus. The question has been aptly asked by Ohlshausen and Veit[2], why should so homogeneous a structure as the corpus uteri become divided during labor into two parts so radically different in function as the upper and lower segments of the uterus? The assumption that the lower uterine segment is the expanded upper part of the cervical canal, although still unaccepted in many quarters, affords the best, indeed the only explanation yet advanced.

Exact data are, of course, difficult to obtain, and, as was to be expected, frozen sections have not afforded conclusive results. A recent case, however, reported by Hahl[3] of Helsingfors, is highly significant, and deserves more attention than it seems to have received. In this case labor was long delayed by a contraction of what during labor was, from its high level, supposed to be the so-called ring of Bandl. Examination at the end of the puerperium, however, showed that the difficulty was a stricture, probably congenital *of the internal os*. This conclusion was confirmed and rendered seemingly impregnable by the fact that microscopic examination of a section taken from the location of the stricture gave the characteristic anatomical peculiarities of the cervical mucous membrane.

A few cases of this kind would suffice to demonstrate that what we have been accustomed to call the ring of Bandl is really the internal os, and to show that post-mortem appearances cannot always be relied upon to explain vital phenomena.

But to return to the condition of the cervical canal during the latter weeks of pregnancy. The majority of our patients are multiparæ, and it is in connection with this class of cases that difficulty in the diagnosis of beginning labor is most likely to exist. In the great majority of cases, contrary to the opinion sometimes advanced, there is dilatation of the entire canal, including the internal os. In nearly every case one or two fingers may be passed through the internal os to the presenting part without the slightest difficulty. The internal os is smaller and more tense than the external os, the relaxed and yielding margins of the latter presenting a marked contrast to the tense and resisting ring of the former. The canal, taken as a whole, resembles an inverted funnel, the internal os being smaller than the external. This is best appreciated when the parts below the internal os are put upon the stretch by the separation of the examining fingers within the canal. The above picture represents the condition of the cervix in the average multipara during the last few weeks of pregnancy. If the antepartum examination of pregnant women proves anything at all it proves that in multiparæ dilatation of the cervix, including the internal os, is no evidence of labor.

The writer has been called to see a supposed case of delayed first stage, the diagnosis being based upon cervical dilatation, combined with the ill-defined pains so common in multiparæ during the latter weeks of pregnancy, only to find that the internal os still bore that relation to the remainder of the cervical canal normal in multiparæ, while, on the other hand, it has happened more than once that he has accidentally discovered the existence of a previously unsuspected labor by finding beginning disappearance of the internal os.

Dilatation of the cervical canal, including the internal os, even to the point of admitting two or more fingers, may mean nothing. Dilatation of the internal os in such a way that what is left of the canal of the cervix begins to form part of the uterine cavity means beginning labor. Only those contractions which are accompanied by this kind of dilatation deserve the title of "labor-pains." At first the change can only be noted during the pains. As labor advances it becomes appreciable during the intervals.

An excellent illustration was afforded in a case in which labor was accidentally discovered during an antepartum examination. The canal was almost cylindrical even at the level of the internal os, but the latter had lost its tense and resisting character, and was as large or a little larger than the external os. This led me to question the patient, who admitted that she had been having pains for some time. These pains had not been sufficiently severe to attract the attention of those about her. It is evident that in her case and in many others the history taken in the usual way would lead one to believe that the first stage of labor is much shorter than is really the case.

It is true that the internal os may re-contract, but this exception is so rare as only to prove the rule. Indeed it is probable that this re-contraction occurs only when some abnormality is present, *e. g.*, after manual dilatation or when the descent of the ovum is prevented by adherent membranes.

In primiparæ the external os is firm and the canal cylindrical or spindle-shaped rather than funnel-shaped. The degree of dilatation is much less, the external os, as a rule, barely admitting the tip of the finger. In some cases, however, the examiner will be surprised to find that one or even two fingers may be passed without difficulty through both orifices.

These facts, of course, are not new. They are found scattered here and there through the literature of obstetrics. They are familiar to those who have interested themselves in antepartum examination as it is conducted in modern maternity hospitals. Many textbooks, however, mention them only in part or not at all, thus leaving the student to make a diagnosis of beginning labor while in entire ignorance of the condition of the cervix and its canal at the time when labor begins.

It is a striking fact and one highly complimentary to the careful methods of the old masters of the obstetric art, among whom may be mentioned Leishman, Meadows, Barnes, and others, men who concentrated their attention not upon gynecological or pseudogynecological technique, but upon that most wonderful of all the wonders of nature, the history and phenomena of pregnancy and labor, that in the older works is to be found a far more accurate presentation of the subject than in most modern ones. Here, as elsewhere, is illustrated the fact that it is not well to lay aside the old books altogether.

It is no wonder that the modern medical student is sometimes bewildered. He will find in standard textbooks the astonishing statement that the cervical canal remains closed until the very beginning of labor, and he is also told that dilatation of the cervix and obliteration of its canal are the chief objective signs of labor; but if he is an observant man and has opportunities for examination, he will find, to his surprise, that occasionally in primiparæ, and, as a rule, in multiparæ, the cervical canal is dilated for its entire length to the point of admitting one or two fingers long before labor begins, and that, especially in multiparæ, obliteration of the canal usually means not only that labor has begun, but also that a large and, clinically, an important part of the first stage has been completed. Unless, however, he is taught these things at the outset of his practical work, he will learn them only as the result of many mistakes, much personal inconvenience and chagrin, and perhaps at the expense of the welfare of his patient.

In the interest then of accurate teaching, a restatement and an emphasizing of these facts seem not only justified but imperatively indicated.

It is a curious and interesting fact that in multiparæ the cervical canal during the latter part of the first stage assumes a shape much the opposite of that which obtains before labor begins. The funnel is no longer inverted—it is the external os which is put upon the stretch during the uterine contractions, and which is now tense and resistant, while the internal os, though still plainly appreciable, becomes softer and more yielding. An appreciation of this fact is especially important from a clinical standpoint, since in multiparæ the internal os forms the chief barrier to delivery. With the disappearance of the internal os the chief obstacle has been removed and labor often progresses with surprising rapidity.

There is usually little difficulty in determining the commencement of labor in primiparæ. As a rule, the cervix remains closed until labor begins, and by the time that dilatation is noticeable the other signs of labor are unmistakable. In those cases in which the canal is dilated before labor the diagnosis may be made in the manner already described. The student should have impressed upon his mind the fact so often ignored or unnoticed that the evidences of beginning labor are not the same in primiparæ as in multiparæ. With reference to prognosis he should remember that dilatation of the internal os is the diagnostic index of the progress of the first stage of labor in multiparæ as is dilatation of the external os in primiparæ.

In cases of over-distention from any cause, *e. g.* hydramnion or twin pregnancy, the canal may be practically obliterated before the advent of true labor. In these cases cervical dilatation may proceed very slowly or cease altogether. This is usually attributed to paralysis of the uterine muscle from distention. As a rule, however, rapid expulsion of the uterine contents follows rupture of the membranes, and hence the delay in the first stage is best explained by the fact that the part of the amniotic sac in relation with the cervix is a small segment of a large spherical surface instead of a conical protrusion, and hence proves entirely inefficient as a cervical dilator. In these cases it is difficult to say at what time the first stage of labor begins. Premature labor is the rule. Before the normal limit of gestation has been reached the extreme distention provokes uterine contractions, which, for reasons just stated, may be ineffectual, and the patient's suffering may be indefinitely prolonged.

These cases are among the most puzzling and trying for the young accoucheur. In hydramnion external palpation is unsatisfactory, and if the distension is not extreme it may be difficult to account for the delay in dilatation. The ease with which ballottement of the relatively small and very movable fœtus can be practised is, however, highly significant. The artificial rupture of the membranes at once establishes the diagnosis and removes the difficulty. It is followed by rapid dilatation of the external os and rapid completion of delivery.

A discussion of the symptomatology and management of hydramnion and other conditions involving excessive uterine distention has no place *per se* in the treatment of the subject at hand. The clinical phenomena of hydramnion, however, afford an excellent illustration of the fact that in many cases it is difficult to draw a sharp line of distinction between the termination of pregnancy and the beginning of labor, and of another fact to which I shall again have occasion to refer, *viz.*, that in many cases of labor not ordinarily classified as premature or abnormal the immediate cause of labor is by no means identical with that which obtains in cases strictly physiological.

What is the cause of the very short duration of labor after rupture of the membranes, in the case of a multipara suffering from hydramnion? The cervical canal has already been practically obliterated and most of the resistance has been overcome. The condition is analogous to that present in a normal multiparous case in which the first stage is half completed. The ring of Müller or clinical internal os, which is the principle obstacle to delivery in multiparæ, is not present, and the resistance offered by the external os and vagina has been largely overcome in previous deliveries. The only obstacle to the rapid expulsion of the fœtus is the mechanical impossibility of effectual uterine contractions. With the diminution in the bulk of the uterine contents which follows rupture of the membranes this obstacle is removed. An additional reason, but one which, of course, has no bearing upon the comparison, is that the fœtus is usually small.

A knowledge of the condition of the cervix during the latter weeks of pregnancy and the early part of labor not only throws light upon the diagnosis of beginning labor, but affords the best answer to the question, What is the immediate cause of labor? According to Bayer[4], the unfolding of the cervix is normally arrested at a fixed, not an accidental, point, in the canal, corresponding to the insertion of the retractor muscles. This point varies somewhat in the individual case, but is nevertheless relatively a fixed one.

Time and space forbid a discussion of the complex subject of the uterine musculature. The main point, however, is that the resistance offered here is greater. This increased resistance is due, in part, to muscular reinforcement, but chiefly to the presence in the lower part of the cervix of a much greater amount of connective tissue than is to be found in its upper part. It is with the dilatation of this part of the cervix that true labor begins. May we not then assume that when cervical eversion has gone on until it is met by this resisting ring—or, in other words, until there is beginning dilatation of the clinical internal os or ring of Müller, the irritation of the great cervical ganglion, with its relatively enormous nerve supply, derived from both the central and sympathetic nervous systems, is sufficient to cause those characteristic contractions which signalize the closing scene of this great physiological drama, and herald the onset of true labor. Uterine distension, with gradual cervical eversion, the primary cause, cervical irritation, produced by the continuance of eversion beyond a fixed point, the immediate occasion, of labor. Viewed in this light, the efforts of nature harmoniously directed toward one point afford an explanation of the cause of labor at once complete and satisfactory, and doing away with the medley of explanations, some plausible, others fanciful, whose very number shows how unsatisfactory each one must be.

The effect of cervical stretching in causing uterine contractions is universally admitted. The tendency to premature labor in conditions of extreme distension is also significant, and many other confirmations of this theory which time and space forbid us to consider, but which will readily occur.

A highly interesting illustration was recently afforded in a case in which labor was induced because the patient, who had already been delivered of one dead child at term, was two and one-half weeks over time. The cervix was manually dilated. Characteristic labor pains at once appeared, but soon ceased and were followed by eighteen hours of quiescence. Examination showed that in consequence of a decidual endometritis the membranes were attached on one side to the uterus, thus preventing the descent of the ovum into the cervix. The membranes were ruptured, the head at once descended into the cervix, the contractions recommenced, and in about six hours the patient was delivered of a living child.

Cases like this tell with a plainness which cannot be misunderstood the part played by pressure upon the cervix in the initiation and continuance of labor.

It has seemed to the writer that a consideration of the results of the various methods of inducing labor should aid in the solution of this question. The Krause method, the introduction of a foreign body in the shape of one or more bougies, while, perhaps, the most popular, is notoriously slow and unreliable. A method which much more closely imitates the natural mechanism is the introduction of a conical rubber bag, the smaller end of which enters the internal os in the same manner as does the distended amniotic sac in the first stage of labor, traction being made as necessary. This method has recently been subjected to a thorough test by Rubeska of Prague,[5] and Vorhees[6] of New York, who have found it, as might have been expected, the most certain method yet employed for the induction of labor. If then we find that eccentric pressure from within outward applied to the ring of Müller is more effectual not only in the acceleration but in the induction of true labor than the insertion within the uterus of a foreign body, we may reasonably conclude not only that the mechanism of labor is more closely followed, but also that the causative force of labor is more closely imitated. The fact that dilatation of a certain part of the cervical canal is coincident with the beginning of labor proves nothing, but the additional fact that artificial dilatation of this part of the canal is the most certain method of inducing labor is highly significant.

Bayer[7] objects that pressure upon the ring of Müller cannot be the cause of labor, since labor may begin before this point is reached. With all deference to the opinion of this industrious and gifted teacher, whose epoch-making work in uterine morphology has never been equalled, this objection can hardly be admitted.

In fact, the effort to make some one factor the cause of labor in every case is largely responsible for much of the confusion which now exists. It is perfectly plain that many agents other than cervical stretching may initiate labor by causing uterine contractions. We are seeking, however, not for every unnatural influence which may interrupt pregnancy, but rather for the immediate cause of labor, strictly normal.

If it be asked why does labor fall upon the two hundred and eightieth day of gestation, the answer is that we have no means of knowing that it does. Every practitioner knows how unreliable are the ordinary methods of estimating the duration of pregnancy. Ahlfeld's[8] tables showed a variation of ninety-nine days, and even if we exclude a large proportion of the cases, 14 per cent. in which premature labor might be surmised, and 6 per cent. in which pregnancy was thought to be prolonged beyond the forty-first week, we have in the balance of cases a variation of three weeks, and even if it be granted that the period required to bring the human ovum to maturity is in all cases substantially the same and that this period corresponds within narrow limits to a certain degree of uterine distention, these facts could be easily paralleled in other natural processes, and would be intrinsically less remarkable than many other mysteries of the scheme of reproduction.

Other causes, such as decidual separation, monthly congestion, and so on, if admitted would seem to act in most cases as accessories; that is, as agents increasing the normal strain upon the upper part of the still unfolded cervical sphincter rather than as direct causes of labor.

The painless contractions of pregnancy, whose rôle has so long been a matter of dispute, are best explained as the reflex response of a uterus subjected to the physiological irritation of distension. Their relation to the gradual obliteration of the upper part of the cervix and the consequent formation of a lower uterine segment is a reciprocal one. The contractions aid in the process of distension and are in turn, stimulated by the very distension which they help to cause, and thus the process continues until it reaches the resisting ring of Müller, the clinical internal os. In contemplating this marvellous mechanism one cannot wonder at the enthusiasm of an ancient writer,[9] or doubt his statement, "Ein Wunder der Natur ist der menschliche Uterus."

The common idea that labor occurs as an interruption of pregnancy caused by some mysterious agent which suddenly evokes uterine contractions, is still prevalent even among physiologists and students of obstetrics. Every one who has carefully watched a case during the last few days of a normal pregnancy knows that the reverse is true. There is no distinct line of demarcation between pregnancy and labor. As Bayer has apty remarked, there is no essential difference between the uterine contractions of pregnancy and those of labor except that the latter are attended with pain. What is the cause of this pain? Its best explanation is to be found in the greater resistance offered by a certain part of the cervical canal.

At the last analysis then, labor is not an interruption but a culmination of pregnancy, a part of a continuous process which extends from conception until uterine involution is complete.

Cervical irritation, it is true, has long been regarded as a cause of beginning labor. Du Bois and his followers held that "complete obliteration of the cervix involves the highest grade of physiological development to which its fibers can attain,"[10] and that the sphincter fibers do not become susceptible to reflex cerebrospinal irritation until such obliteration occurs. The defect in this theory seems to be that, as I have previously stated, ordinary labor progresses for some time before cervical obliteration is complete.

Knüpfer[11] and Keilmann[12] hold that the immediate cause of labor is the mechanical irritation of the cervical ganglion caused by the gradual unfolding of the cervix. This is certainly a near approach to the theory which I have ventured to advance, but overlooks the fact so well demonstrated by Bayer, and which is confirmed by analogy and clinical experience, viz., that beginning labor corresponds in normal cases to the dilatation of a certain fixed point in the canal—the ring of Müller—the clinical internal os—the ordinary physiological limit of cervical eversion.

Various writers have compared the emptying of the pregnant uterus to the emptying of other hollow viscera, *e. g.* the bladder and rectum, but the analogy, while close, is by no means complete. The bladder and rectum must be frequently emptied and pressure upon the sphincter affords the impulse to contraction. The emptying of the pregnant uterus, however, must be delayed, and hence it would seem to be a wise provision of nature that the true cervical sphincter is not at the internal os but below it.

To sum up: The statement made in many textbooks that the cervix maintains its entire length during pregnancy is incorrect.

The statement sometimes made that the canal of the cervix remains closed until the beginning of labor is also incorrect. Usually in multiparæ, and occasionally in primiparæ, the canal including the internal os is dilated to the extent of admitting one or two fingers two or three weeks before labor begins.

Dilatation of the external or internal os or of the cervical canal is not *per se* an indication of beginning labor.

Dilatation of the clinical internal os or ring of Müller in such a manner that it begins to form part of the uterine cavity is at once the anatomical commencement and the diagnostic sign of true labor.

Dilatation at this point is the final result of uterine distention and consequent cervical eversion.

Dilatation at this point, owing to the greater resistance offered, by its effect upon the cervical ganglion, and the consequent reflex awakening of effectual uterine contractions, is the physiological cause of labor.

SOME VARIETIES OF SURGICAL TUBERCULOSIS, WITH SPECIAL REFERENCE TO A NEW METHOD OF TREATMENT.

By L. F. GARRIGUES, M.D.,
NEW YORK.

OF all microbic diseases seen by the surgeon, surgical tuberculosis ranks second in importance only to those produced by the pyogneic microbes. It is a mistake to suppose that it only interests the surgeon; on the contrary, many of its phases come within the scope of the general practitioner. For instance, tubercular adenitis. There is no disease that I know of so common and so carelessly treated by many. The fact seems to be that practitioners do not realize that almost all the cases of chronically enlarged glands are tubercular and that eventually they frequently cause the death of the patient for want of timely and proper treatment. However, to understand the subject thoroughly, it will be better to commence at the beginning and follow the deadly bacillus from the beginning of its career through the various phases of its existence to the end.

It is a law of nature that all animal and vegetable creation must fight for existence, and that only the fittest survive. The life of the tubercle bacillus is no exception to the rule, as you will readily see. Born, frequently in the chest of some consumptive, it is expectorated from its congenial retreat. The sputum dries and the bacillus lies dormant, sometimes for long periods, blown about in the dust. Finally, it settles on an eczematous patch, or a mucous membrane that is fissured, or the seat of catarrh, and the moist warmth revives its activity, and the fight for existence goes on. It breeds others of its species, and in numbers they go to attack the deeper lying structure, choosing, as a rule, the lymph spaces as an avenue of ingress. Here the first opposition meets them in the shape of leucocytes, who take many of the intruders into their protoplasm and their digest them.

But if the bacilli are too great in number to be so disposed of, or if the leucocytes are not strong enough, through a lowering of the body vitality, they are consumed by the bacilli.

The bacilli now float along in the lymph channels until they meet an obstruction in the shape of a lymph gland, a terminal branch of a nutrient artery of a bone or place where a slight injury to the tissues has taken place, and there they settle.

A number of cells are formed around the bacilli, and we now have a tubercular nodule so small that it can only be seen with the microscope. Many of these coalesce, and we get a nodule which can be felt and seen; it is composed of epithelial cells, leucocytes, and giant cells.

Giant cells are simply cells that have taken up a greater amount of nourishment than their fellows in the shape of leucocytes that have undergone fragmentation.

As the tubercle grows its center undergoes cheesy degeneration. This cheesy material contains few or no bacilli, but many spores, as animals inoculated with it quickly develop tuberculosis. Lastly, this cheesy center liquifies, and then we have a so-called tubercular abscess. This name is misleading, as the material is not pus, but broken-down tissue débris; this is the material contained in the psoas abscesses and in cold abscesses generally.

Bacilli will not grow in this fluid, as it does not contain the proper nutriment, but they are numerous in the wall of granulation tissue that confines it. But do not gather that in all cases the tissues go through the above-described changes.

The organism has several weapons with which to fight the invader. Connective tissue may form and contract, taking the place of the diseased cells, and thus destroy the bacilli; this is called healing by cicatrization. The disease may then lie dormant for years or never occur, but there is always danger, as the cicatrices contain spores, and these may become active again with lowered vitality of the body.

Calcification may take place, leaving a hard, whitish substance where the disease was located.

Sometimes the area is surrounded by a connective tissue wall; this is called encapsulation, and is much less of a safeguard than the preceding, and, lastly, suppuration may supervene, and if the area attacked by tubercle is a small one, may destroy it entirely, thus effecting a cure, but if the area affected is considerable it will only hasten the end by disseminating the tubercle bacilli through destroying the granulating wall that confines them, besides adding septic absorption to the dangers incurred.

This danger of infection must always be borne in mind when opening a tuberculous abscess, as it is almost impossible, in many locations, especially in children, to prevent subsequent infection. This has led to the adoption by some of introducing a trocar into the abscess, washing it out, and injecting iodoform, glycerin through the cannula. This procedure must be repeated whenever the fluid begins to reaccumulate, until healing takes place. This procedure is particularly advisable in the large abscesses following caries of the spine, and, in fact, in all cases where the original seat of the disease cannot be reached.

Operations for tuberculous processes, even the smaller ones, are by no means free from danger. Most surgeons can, no doubt, recall cases in which their patients died quickly afterward of general miliary tuberculosis. The reason is this, in the process of curetting blood and lymph spaces are freely opened, and infected cells forced into them. That this may follow curetting has been proven by the microscopic examination of the blood. Therefore I cannot concur in the general practice of curetting tuberculous ulcers and abscess cavities.

Nicholas Senn and others advise curetting a tuberculous-abscess cavity thoroughly and suturing it in an attempt to get primary union. He admits that even if he gets the union spores are likely to remain in the cicatrices which may later become active. Now I do not wish to claim that the sharp spoon can be dispensed with in all cases, or even the majority, but when it is possible it should be done.

The procedure that I use on a tuberculous ulcer, for instance, is to apply the butter of antimony to the surface of the ulcer and reapply it when the slough separates, which takes about four days. I continue the application until the granulations show a healthy cherry color. I lay considerable stress on the presence of whitish opalescent granulations that bleed easily, as an index of a tuberculous condition, as long as there are any of these present the treatment with the butter of antimony must be continued, the moment all granulations are cherry red, all tuberculous tissue, spores and all, have been removed, and the wound heals rapidly.

One should never try to make a tuberculous lesion heal with unhealthy granulations, as the bacilli are still present and simply burrow deeper, invade new tissues, and finally may destroy the patient. A frequent way in which the latter occurs is by the emptying of tuberculous products into a vein, which will be followed with great certainty by general miliary tuberculosis.

It is advised by Nicholas Senn to treat lupus, if anatomically possible, by excising the area involved and performing a primary Thiersch skin graft. This treatment, to my mind, is objectionable, because all the infected tissue may not be removed, and because serious tissue defects remain.

The treatment with the butter of antimony is, in my opinion, better and safer.

The use of caustics has been condemned because their action is not deep enough, but this objection does not hold good for the treatment with butter of antimony, as its action extends in these cases about one-half inch in depth after a single application.

The butter of antimony is an almost unknown substance among physicians, although it is official in the British Pharmacopea. It is used mostly in veterinary surgery to clean out gangrenous surfaces. If applied on the healthy skin, no caustic effect is produced; if on a healthy granulating wound, only a very thin slough follows its use; but if the tissues are degenerated, a most energetic action results.

The slough varies in thickness from that of a piece of paper to more than one-half inch, according to the amount applied and the degree of tissue degeneration present.

Sloughs should not be pulled off, but should be left to separate, so that, if possible, not a drop of blood is lost in the process, because every torn vessel may be the avenue of the dissemination of the disease.

That the great majority of chronic inflammations of the lymph glands are tuberculous, has been repeatedly proven by clinical experience, microscopic examination, inoculation, and cultivation experiments I will not here go over the pathology, as the tubercle, in its various locations, follows the same course, only modified by the character of the tisues it invades, therefore I will only call attention to the difference in the results of the inflammation in the different tissues.

After a gland has become infected, it gradually enlarges, very rarely, however, exceeding the size of a walnut. The larger masses frequently felt are composed of two or more glands that have coalesced after the tuberculous process has made its way through the capsule of the gland, thus giving rise to a periadenitis. The process extends from gland to gland, following the line of the lymph channels, the first one being the largest, and gradually diminishing in size, until the last one may not be larger than a split pea.

If the process is permitted to continue, it extends from gland filter to gland filter, until the last one is passed, and then general miliary tuberculosis rapidly supervenes as the tubercle bacilli have entered the general circulation.

At first the glands are small, hard, freely movable bodies, not tender on pressure, but when the process bursts the capsule of the gland, a tuberculous periadenitis develops, and then they become adherent to the surrounding tissues.

Not rarely there is a secondary infection with pyogenic microbes, and then fever, pain, and tenderness are present. Now the question arises, What shall we do for these cases? How can we defeat the enemy? The answer must vary with the stage of the disease.

Dr. Nicholas Senn advises to operate as early as possible and remove the glands, and if the disease recurs, to repeat the process. As for medication, cod-liver oil, iron, and arsenic are chiefly recommended.

It has become my practice never to operate on tuberculous glands in their early stages until I have had the patient under treatment for one to two months; if they do not then markedly shrink, I remove the glands.

Four indications should be met in the treatment. First, the stomach must be put in perfect order and kept so—this I regard as very important; second, the appetite must be stimulated; third, the blood must be enriched, and, fourthly, an alterative must be given that has special selective action on the glands.

I have never seen any benefit from cod-liver oil, and, as it upsets the stomach and interferes with the appetite, it is positively harmful. Iron is of benefit only if the stomach is in excellent condition.

After putting the digestion in order, I give my patient a mixture of iron and nux vomica before meals to enrich the blood and stimulate the appetite, and to adults a teaspoonful of the syrup of hydriodic acid in a half glass of water after meals; children receive a proportionate amount.

The patient is kept out of doors as much as possible, and is directed to drink much milk—where the patient is thin, as much as a pint every two hours.

Under this treatment, continued from one to two months, the glands usually shrink markedly, and in many cases can scarcely be felt. The patient gains weight and the anæmia disappears.

If at the end of this time the glands have not become markedly smaller, they should be removed, but this is the exception if treated in their early stages.

I have treated a number of patients successfully by this method, who were getting steadily worse under administration of cod-liver oil, creosote, etc.

If the caseous material has liquified, we are not likely to get the process arrested without removal of the glands. But even after the glands have been removed, the patient should be kept on the syrup of hydriodic acid for a long period, to prevent a recurrence of the disease.

Iodine seems to be the one drug that seriously interferes with the growth of the tubercle bacillus, whether administered in the shape of Lugol's solution, used in solution to irrigate cavities, or in the shape of iodoform.

If a periadenitic has set in, the operation must include the tissue surrounding the glands, so that, if possible, not one speck of infected tissue is left behind. Not infrequently there is a secondary infection with pus germs, either through the tubercular abscess having made its way to the surface, or through pyogenic microbes that have entered the circulation by way of the intestines, abraded skin, etc. If this occurs the glands should be enucleated if possible, but, as you will readily see, the operation is now much more dangerous, both as to immediate risk on account of danger of pyogenic infection, and as for ultimate results on account of the pus germs having destroyed the granulating walls.

When the suppuration has continued for some time the glands become densely adherent to their surroundings, and the operation of their removal, particularly in the neck, has become one of the most difficult in surgery, in many cases it is then impossible to remove all infected tissues. In these cases the common, but quite inadequate practice, is to curette the sinuses and inject iodoform glycerin. In this class of cases I have found the butter of antimony particularly valuable.

If a tortuous sinus leads down to the glands, the first thing to do is to slit it up, so that the infected tissue is well under the eye. One should never apply the butter of antimony in a long sinus, as the resulting slough must be able to separate and be freely eliminated. When I first began to use this treatment I applied it in a sinus leading down to carious bone in a case where the disease had recurred after a resection of the knee-joint. The following day the patient had a temperature of 103°F, with a chill and excruciating pain, which continued until the slough had suppurated and been thrown off.

The manner in which I treat these cases can perhaps best be illustrated by recording a peculiar case that I treated with the butter of antimony. The patient was a child eight years old that came to me with an ulcer of the neck just below and behind the angle of the jaw, the floor of which was composed of two large glands the size of walnuts, covered over with the characteristic tubercular granulations and suppurating freely. Below, other glands could be felt in considerable numbers.

The child had been treated for eight months by a prominent surgeon, who had at first tried to enucleate the glands, but had to desist on account of the severe hemorrhage that followed every every attempt at enucleation. The child had then been treated by dressing the wound with iodoform, but was steadily getting worse when she came under my care. I washed the surface with a 2 per cent. solution of carbolic acid and applied the butter of antimony freely to the surface of the glands and the infected ulcer generally, and dressed the wound with iodoform gauze.

In four days the case was dressed again and the slough, which I here present for your inspection, removed and the process repeated.

After the second application, suppuration had ceased, and the edges of the ulcer began to show the healthy cherry-red granulations, only those covering the glands being still of the whitish, gelatinous character.

From now on only the glands and their immediate surroundings were touched with the butter of antimony. As gland after gland was removed, new ones presented in the ulcer, showing that I was merely assisting nature to get rid of the diseased glands by the road of least resistance.

As we progressed, the glands became smaller and smaller until the last ones could just be distinguished as whitish nodules. In the meantime the ulcer was steadily getting smaller from above, where the first glands had been situated.

The last glands had been removed, and the ulcer was healing, when the child was seized with a violent attack of vomiting, which ruptured a blood vessel in the neck. An ambulance was sent for, but the child died from hemorrhage. The ulcer was at that time about the size of a quarter, shallow, and covered with healthy, cherry-red granulations.

I presume that the removal of the enormous masses of glands that had been piercing on the great vessels of the neck had interfered with the support of the vessels, and the congestion caused by the violent attack of vomiting ruptured one. The child had gained considerably in weight and strength while under treatment.

This is the only death I have had so far following this mode of treatment, and a number of patients have been apparently cured by its use.

When applying the butter of antimony in the neck, care must be taken to locate the great vessels and nerves; the small vessels do not bleed after the application, but I should not like to try the experiment of applying it on the carotid artery.

This method is the only one that I know of that affords a reasonable probability of restoring our patients to health and strength in a class of cases resembling the one described.

During the treatment medication as above described should be kept up.

The incision for the removal of tuberculous glands must necessarily vary somewhat with the position of the glands, but the one most usually suitable extends from just below the tip of the mastoid process to just behind the angle of the jaw, from there downward, following the anterior border of the sternocleidomastoid muscle down to the clavicle, if necessary. If the posterior chain of glands is enlarged, the lower end of the incision can be curved backward. If the deep layer is involved, the sternocleidomastoid must, sometimes, be cut in half, the glands removed, and the muscle sutured with chromicized catgut.

In making the incision one general rule should always be followed: Make it so large that all glands can be removed under guidance of the eye. The most useful instruments for enucleation are the finger and a blunt pair of scissors curved on the flat. If possible the whole chain of glands should be removed together in one string, so as to avoid infecting the tissues.

Occasionally, the gland masses are so intimately adherent to the internal jugular vein that this must be ligated and severed; this is much better than to run serious risks of wounding it accidentally.

When all glands are removed I suture the adipose and muscular tissues with catgut and unite the skin with a silk-worm gut subcutaneous Marcy suture. In this way the ugly deforming scars, so often seen after this operation, are avoided, the resulting scar being almost invisible.

As for the advisability of drainage in these cases surgeons differ, some always drain, some never.

I think the best course is the middle one, in an easy case in a well-nourished patient, not too fat, drainage is not indicated, but, when the reverse conditions obtain, it is much safer. The drain should enter at the lower end of the incision and should be of iodoform gauze.

The dressing of these cases is an important element in securing primary union. Plenty of gauze and cotton should be used, and the bandage applied as tight as possible without interfering with breathing, so keeping the surfaces in contact and preventing serious accummulations.

It is well to apply a starch bandage over the muslin bandages to prevent the patient from moving the parts and thus preventing healing.

Tuberculous peritonitis is one of the most interesting phases of the disease, on account of the remarkable effect of operation, although the latest statistics of cures are not as favorable as the earlier ones.

It may be primary or secondary to other lesions. It is much more frequent in women than in men, probably on account of the fallopian tube entering the peritoneal cavity. It may be diffuse or walled off from the free peritoneal cavity.

Its varieties resemble pathologically those that occur in the joints, which is not remarkable, as in both the lesion is in a serous membrane.

The varieties are tuberculous ascites, fibrinoplastic tuberculous peritonitis and adhesive tuberculous peritonitis. As the two latter are not operable we will dismiss them with a few words.

In the fibrinoplastic variety the whole serous surface is covered with masses of granulation, and there is little or no fluid in the peritoneal cavity.

In the adhesive variety the intestines and other abdominal organs are densely adherent to one another and there is little or no exudation.

Tuberculous ascites, the important variety from a surgical point of view, is also the most common. It may be localized or diffuse. The peritoneum is studded with a number of small tubercles and its cavity filled with ascites that may be clear or slightly opalescent.

In women the bacilli not rarely enter through the fallopian tube and are here walled off by granulation tissue.

At this stage it is a serous accumulation, walled off from the free peritoneal cavity, later as caseation and liquifaction take place the fluid contains cheesy masses and has the microscopical appearance of pus.

In tuberculous ascites there is little or no pain except the discomfort caused by the ever-increasing ascites. In some of these cases the distension is something enormous. The diffuse form gives rise to physical signs identical with other forms of ascites.

The diagnosis must often be made by exclusion, and in some cases by examination of the fluid withdrawn for tubercle bacilli.

Having excluded heart, liver and kidney disease, we have still to think of a cancerous condition impinging on the peritoneum, and chronic nontuberculous peritonitis.

The localized form has often been mistaken for an adherent ovarian cyst, but the diagnosis can usually be made by the irregularity of the contour in the tubercular peritonitis, and by the fact that the uterus and surroundings are densely adherent, so much so as to be immovable.

The treatment advocated for these cases is laparotomy and drainage with iodoform gauze. I recently operated on a case of the circumscribed variety, in a young woman who had an irregular, slightly tender mass the size of a large fist, on both sides of the uterus.

Indistinct fluctuation could be felt in the masses The only question of diagnosis considered was between pelvic abscesses and tuberculous peritonitis; as the treatment for both is practically the same, a diagnosis between them is not important. However, a tuberculous family history, absence of chill, very slight or absent fever, and slight pain and tenderness would point toward a tuberculous process.

An incision one inch in length was made in the vagina to the side and posterior to the os uteri. Through this incision a forefinger was introduced and gradually worked toward the center of the mass, taking care not to open the free peritoneal cavity.

The finger, after penetrating the granulation wall, entered a cavity; a gush of pus-like material, containing cheesy masses, followed. The cavity was thoroughly curetted, and a large T-tube inserted, after which iodoform glycerin was injected. The procedure was repeated on the opposite side, which was found to contain a clear fluid, thus showing two stages of the process in one case. The cavity was washed out daily with antiseptic solutions, and occasionally with a solution of iodin. Recovery was rapid and uneventful.

The favorite seat of tuberculosis in bones is near the epiphyseal cartilage of the long bones, the bacilli locating in the terminal branch of the nutrient artery.

The pathology is the same as that of tubercle elsewhere, with the addition of characteristic wedge-shaped pieces of necrosed bone, with the base of the wedge toward the joint, that form on account of the thrombosis that takes place in the nutrient artery.

A process of decalcification surrounds the lesion. As long as this continues the process spreads, but when osteosclerosis takes place the disease becomes circumscribed.

The general symptoms of joint tuberculosis may be very misleading, as patients with quite extensive bone disease may be in possession of good health. Konig has called attention to the diagnostic importance of a constant slight elevation of temperature, observations being carefully made for weeks, sometimes only ½°F. above normal, as a means of diagnosis. The temperature is usually elevated at night. The amount of pain depends on the tension, and may be slight or acute. It is more severe at night. The pain is often referred to a distance, for instance, in hip disease, where the bone is involved, to the knee, and in caries of the spine to the stomach.

Tenderness localized near an epiphisis is one of the most characteristic and constant symptoms. Swelling only comes on late when the disease has invaded the soft parts.

Atrophy of muscles is usually present in greater or less degree, but not so markedly as when the joint is involved.

Puncture with a steel needle into the tender point is, in doubtful cases, a valuable diagnostic measure as the needle will readily penetrate the decalcified areas.

Various methods of treatment are advocated, but to discuss them all would take us outside of the scope of this paper.

Nicholas Senn recommends incision, a thorough opening with a curved chisel, and the removal of all infected tissue with a sharp spoon, afterward he implants iodoformized, decalcified bone chips, and sutures the soft parts in an attempt to get primary union.

Others, after cleansing the cavity, pack it with iodoform gauze and allow the wound to heal by granulation.

A valuable addition to the latter mode of treatment is to cauterize the bone thoroughly with a Paquelin cautery, as it not only kills remaining bacilli, but causes an osteosclerosis to surround the cavity.

I have seen so many local recurrences of the disease after these methods of treatment that I have given them up in favor of the treatment with the butter of antimony.

It is practically impossible, in my opinion, to curette a cavity so thoroughly that one can be sure no bacteria or spores remain.

Therefore after curetting as thoroughly as possible I prefer to apply the butter of antimony over the whole infected surface, and repeat the proceeding every four days until the appearance of cherry-red granulations assures me that I have to deal with a healthy granulating wound.

PRIMARY CARCINOMA OF THE VERMIFORM APPENDIX.

By D. S. D. JESSUP, M.D.,
ASSISTANT PATHOLOGIST TO THE WOMAN'S HOSPITAL; ASSISTANT SURGEON TO THE VANDERBILT CLINIC,
NEW YORK.

THE specimen was removed at the Woman's Hospital in April, 1902, by Dr. Clement Cleveland. The patient was a woman, thirty-six years old, who had had two children and five abortions. Since the last abortion she had suffered with pain in the left inguinal region, and the operation was undertaken for disease of the uterine adnexæ. Abdominal incision showed a cyst of one ovary, which was opened. The appendix was bound down with adhesions, and was therefore removed. The patient made an uneventful recovery.

The gross examination shows an appendix six cm. long. At the junction of the middle and outer thirds it is bent at a right angle. There is a constriction at the bend, and beyond this a dilatation giving a diameter of 1 cm. The proximal two-thirds are 5 mm. in diameter. The peritoneal coat appears smooth, although adhesions were present at the time of the operation. Section shows thickening of the wall in the proximal two-thirds, leaving a narrow lumen here. At the bend the lumen is obliterated. In the dilated portion the muscular coat appears as a thin shell, and the space within is occupied by a tumor mass of firm, yellow tissue.

Microscopical Examination.—Section of the tumor shows an adenocarcinoma. The new growth has replaced the structures of the mucosa and submucosa, and its cells are infiltrating the muscular coat. The cells are grouped in alveoli of various sizes and shapes, and between the alveoli is a small amount of muscular and connective tissue. In the alveoli which show a lumen the cells are cylindrical in shape; in other places they are polygonal. The middle and proximal portions of the appendix are not invaded by the new growth, but there is a marked activity of the germ centers of the lymph nodules. Apart from the rarity of this condition, the case is of interest on account of the absence of any symptoms pointing to disease of the appendix, so that its discovery was an accidental one.

A number of cases in which carcinoma of both appendix and cæcum have been found have been reported, and Kelly[1] has collected seventy-nine such cases. These, however, cannot be considered in determining the frequency of primary carcinoma of the appendix, for there was no evidence to show that the growth originated in the appendix. Other cases of carcinoma confined to the appendix alone I have not included in the following list, because the diagnosis appears to have been made on gross examination alone. The thirteen cases collected are:

1. Reported by Beger[2]. The carcinoma of the appendix was in a man forty-seven years old, and was found in an operation on a sinus following drainage of an abscess in the right iliac fossa. At autopsy the abdominal lymph nodes were found to be invaded.

2. Reported by Stimson[3]. The appendix, cre

moved at operation from a woman forty-four years old, was four inches long and in a state of "cancerous degeneration." She had had two attacks of appendicitis, the first ten years before.

3. Mossé and Daunic[4] report the case of a woman, fifty years old, who died of heart disease. The appendix, removed at autopsy, was 4 cm. long and 4$\frac{5}{10}$ cm. in circumference. The new growth occupied the whole length of the organ. There was no history of appendicitis.

4. Wright's[5] case was a patient dying of general purulent peritonitis. A perforation was found at the junction of the cæcum and appendix, and a carcinoma at the tip of the appendix.

5. Of two cases reported by Kelly[1] the first is without clinical history. The appendix, removed at operation, was 11 cm. long, and the tumor was located in the distal portion.

6. The second case was a man nineteen years old. An operation was performed nine days after the first symptoms of appendicitis appeared. The appendix was found surrounded by a small collection of pus. It measured 5 cm. in length, and the tumor was situated at the base.

7. The case described by Elizabeth Hurdon[6] was that of a woman twenty-four years old. There was a history of pain in the right iliac fossa. At operation adhesions were found enveloping the appendix. It was 10 cm. long, and the tumor occupied the middle portion.

8. Rolleston[7] reports an appendix removed by operation from a woman twenty-six years old, who was suffering from her fourth attack of appendicitis. The tip of the appendix was adherent to the uterus, and the tumor was located here.

9. Whipham's[8] case was removed at autopsy, from a woman forty-five years old. There was no history of appendicitis, and death was due to emaciation and exhaustion, caused by the abdominal condition. There was a carcinoma of the base of the appendix, and secondary deposits in the liver, ovary, lymph nodes, and peritoneum.

10. Of two cases reported by McBurney[9], the first was a woman twenty-three years old, operated on after a second attack of appendicitis. The appendix was four inches long, and the tumor, the size of a pea, was located at the apex.

11. The second case was a man of about thirty years, who gave no history of appendicitis. At autopsy Lartigau found a carcinoma of the tip of the appendix.

12. The case operated on by Goffe[10] was a girl of fifteen years, who had had symptoms of trouble with the appendix for one year. The tumor was located at the tip.

13. Harte and Wilson[11] report a carcinoma of the middle third of the appendix. It was removed by operation from a woman twenty-four years old, who gave a history of appendicitis.

The type of carcinoma in the cases where it is described is adenoçarcinoma. Nine of the cases are in women and three in men, and the fact that in most of the cases the condition is unsuspected will tend to maintain its greater frequency in women, because they are more often subjected to abdominal section.

It is noteworthy that two of the cases are under twenty years of age, and four under thirty years. There was a history of appendicitis in seven of the cases, and no history of it in five. The location of the tumor is most often at the apex, being here in eight instances.

In four cases the new growth was found at autopsy, and in the remaining cases at operation; but in no case had carcinoma of the appendix been previous diagnosed.

Routine microscopical examination of all the appendices removed will doubtless in the future show that carcinoma occurs in the appendix more often than has hitherto been thought.

THE VENOUS SYSTEM OF THE TEMPORAL BONE AND ITS RELATION TO THE COMPLICATIONS OF MASTOID DISEASE.*

By SEYMOUR OPPENHEIMER, M.D.,
NEW YORK.

OTOLOGIST TO GOUVERNEUR HOSPITAL; INSTRUCTOR IN LARYNGOLOGY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.

THE relation of infectious processes, either immediate or remote, localized or general, derived from a primary microbic infection of the cavity of the middle ear, including the antrum as a portion of this chamber and the pneumatic cells of the mastoid process, depends in many cases upon the transmission of the infective material by the extensive and complicated venous channels of this region. When it is borne in mind that the aggregate area of the veins is much greater than that of the arteries of the temporal bone and that the veins anastomose one with another so as to produce a complete network throughout the external and internal surfaces and cells of this region, the intimate connection with the sinuses, meninges, and cranial fossæ, readily explains the liability to infection following mastoid necrosis.

In the majority of cases of sinus thrombosis and brain abcess complicating aural suppuration, direct paths of infection, by way of necrosed bone, are plainly visible on examination after the mastoid cortex has been removed, but in a considerable number which is constantly increasing as the importance of the venous system as a carrier of infection is becoming better recognized, the infective material is carried directly to the parts by means of the large or even minute venous channels. As carriers of purulent material or as means by which the septic inflammation may extend from the temporal region to the neighboring parts by continuity, the venous channels present three distinct systems (excluding the sinuses) in relation to the mastoid area. Internally the veins of the brain membranes and especially of the dura are numerous, anastomose freely in all directions, communicate with the pia mater, which in turn sends venous channels into the cerebrum and cerrebellum, and externally they freely communicate with the diploic channels, with the exception of but two, which leave the skull through the spinous foramen to join the internal maxillary vein. The second system, which I am assured is an essential factor in some of the serious cases of mastoid complications, is that of the diploic veins, which channel the middle plate of the skull in a most tortuous fashion, and, while protected to some extent by the other two layers of compact osseous tissue, is yet susceptible to infection, or acts as a carrier of infection, both by intercommunicating with the veins already mentioned and with those externally. The walls of these veins are extremely tenuous and formed only of epithelial cells, and at frequent and irregular intervals dilatations are seen in their caliber, allowing the blood to flow but slowly, and acting as most excellent sites for the development of focal infections.

---

*Presented at the eighth annual meeting of the American Laryngological, Rhinological, and Otological Society at Washington, D. C.

The third group of veins, which is by far the most important in this connection, are those ramifying through the temporal bone and in indirect communication with the diploe of the occipital region, being responsible in isolated cases for the development of osteomyelitis of the occipital bone, complicating extensive mastoid destruction. While a still larger number are in direct communication with the large venous sinuses and cranial cavity, the mastoid emissary vein being representative of the larger vessels, while the smaller blood channels, often microscopic in caliber, ramify freely through the mastoid and petrous portions of the temporal bone and bring the tympanic cavity and pneumatic cells in direct vascular connection with the cranial contents. In pachymeningitis, epidural and extradural abcess, therefore, the infection may be traced from the temporal bone, by way of the vascular and membranous channels, a portion of healthy bone intervening between the two infected areas; these cases being infrequently observed, but nevertheless demonstrate this relation by direct communication between the external system of veins and the collateral intracranial venous circulation.

Another factor in the production of sinus complications, is the natural feebleness of the rate of the blood flow in the veins and the tendency to localize lacunæs of blood stagnation, resulting from the differences of the caliber of the vein as it pursues its tortuous course in this location. As a correlary to the infrequent nasal œdema seen as a minor symptom of venous stagnation, the result of extensive thrombosis, may be mentioned the venous plexus near the pharyngeal orifice of the Eustachian tube, communicating both with the nasal turbinal tissue and the aural region.

By direct communication between the dural vessels and those of the pericranium and lining of the aural cavities, the membrane of which is freely supplied with venules, the meninges may be involved through these vessels which perforate the inner table of the skull. I have seen two cases, both in young adult males, in which, in addition to the other lesions present, there were localized areas of maningitis apparently in communication with aural necrosis, but which proved, on close examination, to be due to direct infection by way of a vein passing from the mastoid cells in close proximity to the antrum and anastomosing with one of the dural vessels; a minute septic thrombus, extending from the suppurating mastoid to the inflamed meningeal tunic. Another fact of considerable importance in this relation, is that the propagation of the infection by the reflux blood current is accelerated and more readily brought about on account of the absence of any definite system of valves in the intracranial veins and sinuses, and, although valves are found more or less frequently in the veins of the mastoid and tympanum, yet it is not rare to see the veins of this region entirely free.

Many of the minute communicating veins empty directly from the bone into the adjoining sinuses, not always by direct channels of any magnitude, but by microscopic channels which form a rich interosseous network. The presence of these vascular canals undoubtedly favors necrotic changes in the mastoid, and they also constitute a channel of infection to the lateral and other sinuses in relation with the organ of hearing. These vascular relations are especially prominent in the child, and, as the pneumatic spaces of the mastoid are further developed, the anastomotic relations between the vascular lining of the cell walls and the sinuses are remarkably free. Although the veins are widely and profusely distributed, they have more or less regularity, and by following certain structural lines, the occult paths of infection may be determined.

Most frequently, when the infection is through the venous channels, the cranial cavity is invaded through the superior and median walls of the mastoid, into the posterior cranial fossa. Possibly the next most frequent channel is by the small vein passing through the tegmen tympani and exposing the middle fossa to infection. Rarely the purulent material may enter through the labyrinth and internal auditory canal. I have observed a case in a child in which this route was followed, as shown at the necropsy, with the production of purulent leptomeningitis; the case being one of chronic infection of the middle ear and mastoid, with an acute exacerbation from an attack of scarlet fever.

Another route, by which this accident may occur, is through the posterior wall of the petrous bone into the posterior cranial fossa; a temporal bone in my possession showing this way of infection most beautifully, inasmuch as there are from six to eight venous channels in the bone directly communicating with the sigmoid sinus. Extremely rare, but not the less important, in the study of the minute venous paths of this region, are the venules which pass through the antrum and lower walls along the fossa for the bulb of the jugular vein and the carotid canal. While both the middle ear and mastoid are involved in the suppurative process, the sinus or cerebral complication, and especially the latter, may be derived from the tympanic cavity and not from the infection in the pneumatic structure of the mastoid. This occurs through the venous plexus of the promontory and the vessels in the inner ear emptying through the internal auditory vein, either by direct branches into the cranial fossa, or indirectly through the meningeal veins into the petrosal, transverse, or petrosquamus sinuses. Another group of communicating veins which require mention in this connection, but which are only indirectly concerned in the production of intracranial complications, are those filling the minute perforations in the posterior wall of the osseous external canal and passing directly backward into the mastoid cells. It being not at all uncommon to have the infection augmented or primarily transmitted to the latter cells, through this group of venous radicles.

Phlebitis of the veins of greater magnitude than those just mentioned, occurs occasionally and the cranial contents are affected by continuity, while in other instances these veins merely act as carriers of septic material, as do the smaller venules. Usually the veins of this class follow the course of the arteries, those on the posterior aspect of the canal and auricle emptying into the external jugular, while those anteriorly join the temporal and facial veins, and although these vascular channels are rarely primarily affected, yet they are of diagnostic importance in the latter stages of sinus thrombosis. "Griesinger's symptom"—that is, œdema of the occipital and nuchal regions—being one of the signs of venous embarrassment dependent upon thrombosis as a complication of mastoid suppuration, and results from phlebitis and obstruction of the mastoid and occipital veins.

While the anterior and posterior condylar veins are often involved by inflammatory extension from sinus changes, œdema and tenderness along the course of their distribution occur as a symptom of considerable importance in obscure cases. Of the same importance as these and as an evidence of circulatory embarrassment due to engorgement of the veins tributary to the sinuses, is the tenderness in the upper portion of the posterior cervical triangle, dependent upon inflammation of the deep vascular channels of the neck. The veins of the labyrinth acting as direct infectious ducts unite to form three main branches, that of the cochlear aqueduct; of the aqueduct of the vestibule and of the internal auditory canal. Unfortunately, it is almost impossible during life to diagnosticate the extension of pus in this direction and only at autopsy and even then infrequently can traces of the phlebitis be ascertained. Cheatle[1] described a case showing the transmission through these larger veins in a most admirable manner. The patient was that of a male of twenty years, who died with symptoms of meningitis. Autopsy showed a suppurative meningitis over the right side with septic thrombosis of the lateral and longitudinal sinuses. The point of special interest and of great pathological importance to the otologist being the discovery of a vein large enough to admit the passage of an eye probe which made a direct communication from the tympanum to the lateral sinus.

Unfortunately, the textbooks on anatomy, and especially on otology, are practically silent in regard to these most important venous channels of the temporal bone, bare mention being made of some and not at all of others, which, it will no doubt come to be recognized, are the carriers of infection to the adjoining sinuses in many cases of mastoiditis.

The mastoid emissary vein, when the subject of phlebitis, plays an important part in the development of pus collections in the posterior cervical region, in connection with necrosis of the mastoid. I have been able to clear up the diagnosis of an obscure purulent condition here, by careful study of the external parts which are covered by the distribution of this channel, the presence of a deep-seated abscess sometimes showing itself quite early, in conjunction with a periphlebitis of this vein. It pursues a most irregular and tortuous course through the bony walls of the mastoid process, either as a single venous channel which, in my experience, seems to be more constant than the other form, where it divides into numerous small channels and makes its appearance on the external surface of the mastoid, through from three to seven minute perforations. In a dry specimen in my possession the internal orifice for the vein measures one-eighth of an inch across, while on the external surface of the same bone it appears through four small orifices, dividing into these smaller vessels in the interior of the bone. The vein is subject to wide variations, both as regards its caliber and distribution, but its most constant course is by curving outward and backward from the lower bend of the sigmoid sinus and passing through the bone emerges in the immediate vicinity of the occipito-temporal suture, usually appearing about one inch posterior to the external auditory canal. When single no two specimens are alike in size, as on the one hand it may be so small as to be hardly visible and have no pathologic or diagnostic value at all, while again it may in size and structure perform the part of a large sinus carrying the blood from the sigmoid sinus to the external jugular vein.

From the standpoint of mastoid complications, the mastoid vein is of much practical value in two aspects; as a carrier of infection from the mastoid cells to the sinus and as an aid in the diagnosis of intracranial inflammation. I have seen one case of acute mastoid disease in which this vein was affected immediately under the cortex, a septic thrombus forming at this point and extending inward occasioned a like result of the sigmoid sinus, but the case reported by Buck[2] presents this mode of infection much more conclusively. In his patient there was an acute inflammation of the middle ear, terminating in a purulent periphlebitis of the lateral sinus, an incision, and counter irritation over the mastoid had been made, but, becoming infected, had led to phlebitis of the mastoid emissary vein, which in turn had directly infected the sinus by continuity of tissue. As an aid to the diagnosis of pathological alterations of the sinus, I have found tenderness and a boggy swelling at the point of exit of the vein of considerable help in conjunction with the other symptoms, and when the symptom-complex is not clearly evident of the intracranial condition, this factor will assume a position of considerable importance. At the same time the signs mentioned are not always conclusive of sinus involvement alone, as the symptoms are sometimes present when there is an extradural collection of pus in proximity to the vein, but at the same time some involvement of the sinus is usually present.

The line of least resistance from the primary focus of infection to the sinuses, meninges, or brain tissue is not necessarily along the thinnest osseous areas or the largest vascular channels, but in many cases the infection passes through minute venous routes, and it is only on these premises that the cerebellar and isolated cerebral abscesses in conjunction with mastoid necrosis, and in which a considerable area of healthy brain tissue intervenes, can be explained. Numerous cases of mastoid abscess affect the intracranial contents, not necessarily through the bones in the line of the least resistance, for I am sure every surgeon has observed cases in which the infected material apparently travelled along the lines of greatest resistance, a healthy barrier of dense bone interposing between the primary disease and its complication. This can only be explained, I believe, by the infection travelling along the microscopic veins, careful examination alone proving the correctness of this assertion. This route is well demonstrated when the infection in conjunction with the mastoid and antrum involves the exceedingly dense structure of the petrous portion of the temporal bone, and while I do not deny that the larger number of cases are readily explained by direct osseous destruction, yet there is a constantly increasing number of cases where the veins are the principal factor.

In this locality we must, of necessity, take into consideration the vast and complicated venous network at the base of the cranium in relation to the large venous trunks of the cervical region, rather than try to explain the route of the infection by the non-resistance of the osseous tissue.

On account of its intimate connection with the mastoid, the lateral sinus, and especially its sigmoid portion, is extremely susceptible to thrombotic changes, while less so are the inferior and superior petrosal, the cavernous sinuses, the bulb of the jugular, and the whole length of the internal jugular vein, involved in the pathological alterations. Not only is the lateral sinus more exposed to thrombotic changes on account of its close relation to the temporal bone, but it is in intimate relation with the other sinuses, and especially with the mastoid emissary and numerous small veins draining the temporal region. Variations in its position and size are so common that for purposes of surgical procedures no reliability can be placed upon external landmarks, although as a general principle Whiting[3] says that if the mastoid is markedly prominent and convex, the sigmoid groove will be found very near the posterior wall of the auditory canal, while if the process is broad and flat, the sinus usually lies quite far behind the posterior wall of the osseous canal. Of importance, from its relation to the other sinuses and especially the internal jugular vein, is the tendency of a localized periphlebitis of the lateral sinus to extend, and with the displacement of emboli, produce septic changes in other organs at remote distances. Being formed at the torcular by the longitudinal sinus, it passes outward and forward to receive the superior petrosal sinus in relation to the petrous portion of the temporal bone, then, as it turns inward to find its exit into the bulb of the jugular, it receives the inferior petrosal. But in addition to this most intimate relation with the venous sinuses and temporal bone, there are also present numerous venous tributaries entering it in all directions from the pneumatic cells and rendering it peculiarly susceptible to septic changes in practically all cases of mastoiditis of any duration.

When the petro-squamos sinus, which carries the intracranial venous blood into the primitive jugular during fetal life persists, the tendency toward pyemia and suppurative meningitis as a secondary infection from otitic sources is greatly increased, and as several cases have been recorded in which the infection travelled by this route, due consideration must be given to it in considering the venous channels in this relation. A. H. Cleveland[4] recorded a case of a boy of six years dying of pyemia of otitic origin, in which the necropsy showed that the petro-squamos sinus was deep and large, while necrosis had taken place at its anterior extremity and pus had infected it, causing a thrombus, which extended backward into the lateral sinus, and in addition to the local changes, a patch of meningitis existed on the same side. After it has fulfilled its fetal functions the anterior opening becomes obliterated, and the small vein representing its remains, opens into the middle meningeal vein. In childhood its presence may still be detected extending from the vein mentioned to the lateral sinus, while in adults it rarely persists, and when present is often so small as to be difficult of recognition. As it is rarely found in adults, and from its large size when present in early life, its relation to septic infection is not of as much moment in the former as in the latter. This being well shown by A. H. Cheatle[5] in two cases which he reports, in one of which, a male of twenty years the vein was found large enough to admit a probe.

Both the inferior and superior petrosal sinuses inosculate with the cavernous and transverse sinuses and by the vestibular vein receives the blood from the labyrinth into the superior petrosal, while through the internal auditory vein the blood is usually received by the inferior petrosal, although infrequently it empties directly into the transverse sinus. In addition there are several small venules inconstant and irregularly distributed, which place the otitic cavities in relation to these sinuses, and when these are infected with the resulting septic phlebitis and thrombosis, the small radicles probably are a common method by which the pus organisms are transmitted to the intercranial cavity. In a case seen by Stirling[6] of a child of seventeen months, with thrombosis of the petrosal, cavernous, and circular sinuses, the infection followed the course of these small veins from the attic into the superior petrosal sinus.

Although the cavernous sinus is not in direct proximity to the auditory apparatus, yet its connection with the lateral sinus by means of the superior petrosal, with the jugular vein through the inferior petrosal and with the surface of the cranium by means of numerous minute veins, renders the symptoms resulting from obstruction of its caliber of considerable importance in relation to the subject under discussion. Occupying a unique relation to the other sinuses by its contents, consisting of the internal carotid artery with its sympathetic plexus, the third, fourth, sixth, and ophthalmic nerves, pressure within its walls upon these important structures often produces symptoms of valuable importance in arriving at correct conclusions in regard to pathological changes in this portion of the vascular system. Stirling first called attention to a sign of obstruction of this sinus, consisting of a moderate degree of œdema or puffiness of the eyelids and engorgement of the opthalmic vein, on the side corresponding to the affected vessel. While, as a result of the interference with the circulation here, the blood is dammed back in the tributary veins, and œdema of the tissues supplied by these channels takes place, at first limited to but one side and later, as the thrombus extends to the adjoining sinuses by way of the circular or transverse sinuses, it becomes marked on both sides.

As the cavernous and the remaining sinuses, in more or less relation to the mastoid region, take but little part in necrosis of this bone and communicate with it but indirectly, little need be said of them in this connection.

Although not primarily affected from the ear, but secondarily by way of the veins and other sinuses, yet they may be of great importance as pathways for the further extension of the thrombotic process; this being shown in a case reported by O. J. Stein[7], in which, in a case of fatal sinus thrombosis, the clot was believed to have extended to the opposite sinus by way of the transverse and circular sinuses. This was not verified by autopsy, but seems very probable in the light of a case coming under my observation in a man of thirty-five years, in which, following mastoid necrosis of the left side, the sinuses were completely thrombosed, including the inferior petrosal on the right side. The clot crossed over the transverse sinus and completely obliterated the venous flow over the entire area mentioned.

In the inflammatory changes of the small veins leading from the temporal bone to the interior of the cranium, the two outer coats of the vessel suffer at first the brunt of the inflammatory attack originating in the mucosa of the tympanum or mastoid cells. They become hyperæmic and later infiltrated with serum and pus. In the early stages of mastoid suppuration, this condition of the emissary vein can readily be detected on operation. This process may go no further, the inflammation spreading along the venous wall without doing serious damage to the parts in transit, or finally cause a localized pus collection or periphlebitis at some distant point within the cranial cavity. Or, as is more commonly the case, the inner coat of the vein becomes cloudy and fissured, disintegrating in part here and there, with the dissemination into the larger channels of small particles of the vascular lining, blood clots, and pus cells. If the vein is not infected, the thrombus, which may form either, remains localized, completely shutting off the further encroachment of the septic process in the mastoid through this particular channel, or it may extend, obliterating the channel with an aseptic thrombus. Or again, it may later become infected and cause sinus thrombosis or brain abscess dependent upon the location of the distal extremity of the vessel. Another salutatory termination which I have observed in a case of old mastoid disease was the complete obliteration of the vein due to fibroid thickening with subacute phlebitis, and while the vein was surrounded by pus and detritus no evidence of infection transmitted through this particular channel could be recognized.

After infecting the lateral sinus the clot may still augment in volume, and in the presence of septic material, small particles may become dislodged and produce pyemic symptoms with localized abcesses in other portions of the body. In the subacute form, with thickening of the vein, there may be local occlusion and the development of a small abscess. Hemorrhage does not usually take place even if the vein is ulcerated through, as it collapses early from the newly-formed fibrous tissue around it and the pressure of the surrounding inflammatory infiltration. Occasionally the vein may withstand the purulent and necrotic changes of the surrounding osseous tissue for a considerable time, until a limited patch of acute phlebitis develops from the violence of the local infection when an opening will ensue, into which the pus organisms and their products will gain entrance; the development of otitic pyæmia therefore is usually in this locality the result of an acute exacerbation of a sub-acute phlebitis.

The minute thrombus or multiple thrombi may form at any point in the vascular network of the temporal bone, following the early stages of acute inflammation of its lining mucosa, and from the localized stagnation of the blood current thus produced, caries will develop at this point. Retrogressively the primitive thrombus may extend into the brain interior by the minute venules running from the surface of the temporal lobe to the superior petrosal sinus and from the anterior surface of the cerrebellum to the lateral sinus, while the process may be reversed, involving the sinuses primarily, or the process may involve the venules which course from the temporal lobe to the dura mater covering the roof of the tympanic cavity. So extensive in fatal cases may the thrombus become, that, extending from sinus to sinus, it may occlude the entire venous channels of the cranial interior. An interesting case of extensive thrombosis, in which the jugular and facial veins were also involved, being reported by Littaur and Mensing[8]. The internal jugular vein is frequently involved in connection with the lateral sinus and a tenderness or cord-like feeling over its course may sometimes be elicited. While another symptom, which has been found of diagnostic importance in some cases but which has proven of little value in my hands, is obtained by laying the finger with sufficient force across the external jugular of the affected side to produce obstructive pressure, the vessel will then show but slight turgescence or none at all, while upon the healthy side it becomes engorged to a pronounced degree if similar pressure be made.

Osteophlebitis of the temporal bone, as described by O. Korner[9] occurs very rarely as a result of the entrance of pus into the small veins from the primary focus of the mastoid, but pyemia from the thrombus and septic detritus is much more frequent, although if the osteophlebitis is at all extensive, pyemic symptoms and multiple abcesses are usually concomitant. A phlebitis of the small veins is one of the most frequent causes, in my experience of otitic meningitis, and the pachymeningitis externa so produced may lead to thrombophlebitis of the larger sinuses or to brain abscess. The extreme difficulty of tracing the course of the infection may be seen by the study of three cases reported by Meier[10], in which the pus was conveyed to the cranial cavity by a phlebitis of the veins passing through the carotid canal.

While the majority of the complications of mastoid necrosis are the result of infection through direct destruction of tissue, yet many cases of sinus phlebitus, brain abscess, and meningitis are directly traceable to infection by way of the small venous channels of the temporal bone, a further study of these venous channels, of which but little is now known, I am confident will elucidate many obscure points in the complex problem of these complications.

A CASE OF EPITHELIOMA OF THE MARGIN OF THE EYELID APPARENTLY CURED BY THE USE OF A SOLUTION OF ADRENALINE CHLORIDE.

By WILBUR B. MARPLE, M.D.,

NEW YORK CITY.

Six months ago I would have said that I had never seen an eye case which had been permanently benefited by the use of adrenaline. But during the last six months I have seen one case which, so far as I know, is unique, and which is, in some respects, so remarkable as to warrant describing it in extenso. The patient was a married lady, about forty-five years of age, in good health, the wife of a business man of this city, referred to me by a fellow practitioner here. She was first seen June 5, 1901, and gave the following history: She has had a small growth on the left lower lid, which began about six years ago, in what she thought was a stye at the middle of the lid (her physician said it started apparently as a meibomian cyst) and this has gradually crept toward the outer canthus. During the past winter it has annoyed her considerably, becoming readily inflamed and bleeding easily, though there has been no pain associated with it at any time.

On the occasion of her first visit, the condition was as follows: The border of the left lower lid was the seat of a characteristic epitheliomatous infiltration, extending from the external canthus and reaching beyond the middle of the lid, in all 18 m.m. in length. The nodular infiltration at the middle of the lid extended downward 6 m.m. and the lid was somewhat notched here. This infiltrated area was more or less red. The nature of the growth was explained to the patient, and its removal was advised, which she decided to have done in the autumn after the hot weather was over. A small portion was excised, and subjected to a microscopical examination, which revealed the characteristic histological picture of epithelioma. She was given a solution of adrenaline as a placebo to instill into the eye every evening, as the growth looked quite irritated. I saw the patient once more early in July just before she left the city for the summer, when I noted that the growth looked much less irritated. I did not see her again till last January, and was somewhat prepared for what I found by a note received in December from her husband, in which he said that the medicine I had given his wife had cured her entirely. This proved to be almost literally true, for I found along the margin of the lid previously occupied by the epitheliomatous growth a clean indrawn cicatrix with the lashes, of course all gone. Only at one spot was there dangling a small shred of the tissue of the growth. The patient reported that she had used the adrenaline (1-1,000) regularly for three months until the end of September. After that irregularly, and had ceased using it altogether since Christmas. After she had used the preparation for a month or so she noticed that little brown scabs or crusts formed on the outer surface of the growth, which fell off either spontaneously or with the least rubbing, as on washing her face. As these little crusts came away the mass became always a little smaller, until it had practically disappeared. During all this time the adrenaline was absolutely the only remedy used in her eye by the patient. To say that I was even more surprised at the result than was the patient is but expressing the truth, for I had given the remedy simply as a placebo to use until the growth could be excised. I am sure the result is cosmetically better than would have followed the use of the knife. I cannot see what else could have produced this remarkable result except the adrenaline, for nothing else was used except that, and simultaneously with the commencement of its employment a growth which the patient had had for six years began slowly to disappear. If the adrenaline was responsible for the cure the explanation is not difficult to seek. The nutrition and blood supply of these epitheliomatous masses is very poor, and the bloodlessness following the use of adrenaline apparently acted like a ligature in compressing the vessels, and gradually the most peripheral portions of the mass died and were rubbed off in small scales. This individual was remarkably susceptible, as I accidentally discovered, to the peculiar blanching effect of adrenaline, for a piece of cotton wet with the solution and laid on the unbroken skin of her cheek would, in five minutes, make the spot as white as a piece of paper. Whether the result here depended upon a peculiar susceptibility of this individual to the adrenaline or whether a similar result can always be obtained in such a case, it is impossible to say. I have at present two similar cases under treatment, but they have been under observation only a short time. If a like result is obtained, then we shall have in adrenaline a most valuable curative agent in dealing with such epitheliomatous growths.

SUMMER DIARRHŒA IN INFANTS AND YOUNG CHILDREN.

By MARTIN J. SYNNOTT, M.D.,

ATTENDING PHYSICIAN TO ST. VINCENT'S FOUNDLING ASYLUM, MONTCLAIR, N. J

Summer diarrhœa in infants and young children is due in almost every instance either to contaminated food or to food of improper quality or quantity. It is a communicable disease, and this fact should be impressed upon mother and nurse by the physician to safeguard other children in the same household, and to guard against reinfection in the infant already ill. Bottles, nipples, cooking utensils, and the hands of the mother and nurse should receive scrupulous and painstaking attention.

Attacks of summer diarrhœa vary in intensity from the simple case of the child who has had two or three moderately loose movements daily, containing a few or many undigested curds of milk and mucus, without fever or constitutional symptoms, to that of the acutely infected child poisoned with organisms of great activity, with vomiting, profuse diarrhœa, pain, hyperpyrexia, and rapid emaciation—the much-dreaded "cholera infantum." We use the term "summer diarrhœa" because the heat is unquestionably an important factor in the etiology of such attacks. We must consider the influence of the hot weather upon the food as well as upon the child. The first consideration is often lost sight of, but, in the opinion of the writer, it is the most important. If the mother and nurse are careless, or are not properly instructed in the importance of preserving the baby's food at a proper low temperature, the bacteria present in all milk rapidly multiply and harmful chemical changes take place. Many families of the middle and poorer classes have no ice. Not infrequently the early milkman leaves his milk bottles standing in the hot morning sun, to remain there until the household is astir an hour or two later. Then, too, domestics are often careless in caring for the milk, and the bottles are allowed to stand for hours in the warm kitchen atmosphere. During these intervals the bacteria in the milk have been rapidly proliferating, and it is no longer a safe food for the young bottle-fed infant. The child is affected by the summer heat because of lowered vitality and lessened resisting power. The functions of the liver and stomach are less active, and in consequence less gastric juice and bile are secreted.

In hot weather milk should always be sterilized or Pasteurized. For a healthy child Pasteurizing is sufficient, while for the child who has already had an attack of bowel trouble, the milk should be thoroughly sterilized. After either process rapid cooling is of great importance, for if allowed to cool slowly, the remaining spores of the bacteria develop new activity in the warm milk. The writer has no patience with those physicians who claim that sterilizing is harmful and unnecessary and "takes the life out of the food." Results of clinical experience teach exclusively that *not* to sterilize or Pasteurize in hot weather, except in certain specific cases and under most favorable conditions, is little short of a crime.

With these facts in mind, it is not difficult to arrive at a rational plan of treatment. An accurate differential diagnosis of the precise lesion and its location is not essential. As a matter of fact, at the onset of the trouble, in most instances no lesion exists. Inspection of the stools seldom reveals more to us than the presence of undigested curds, mucus or other products of intestinal fermentation. A bacteriological examination of the stools is available in only a limited number of cases, and is more or less unsatisfactory.

The first essential point in the treatment of every case of summer diarrhœa is to stop milk feeding at once, whether the child has been breast-fed or not, for a period depending upon the severity of the case. Milk, even though previously sterilized, when undigested in an already infected intestinal tract and at the body temperature, is a perfect culture medium. In a breast-fed baby eight to twenty-four hours is a sufficient period to stop the milk feeding; then it may be resumed, but each nursing preceded by the administration of an ounce or two of sterile water. In the bottle-fed, milk feeding should not be resumed until the movements are nearly normal, and then largely diluted with water and carefully modified to suit the conditions and the symptoms of the patient. Instead of milk in the bottle-fed, some bland, nourishing, and easily-digested substitute must be provided. After an initial dose of castor oil or calomel, no food at all should be allowed until all curds and undigested food have been expelled from the bowel. If the movements are loaded with curds, it is often advisable to repeat the oil in four or five hours. During this interval, sterile water, preferably warm, may be freely given. Usually this will be all the infant craves, the normal appetite for food having been replaced for the time by an abnormal thirst. When food is again allowed, which will be after six to twenty-four hours have elapsed, a smaller amount must be given than was allowed before the attack, but the intervals may be shortened, provided that the two-hour limit is observed. To replace the milk, in very young infants, dextrinized barley gruel is the most available substitute. The objections formerly made against cereal feeding to young infants are now overcome by the ease and simplicity with which the dextrinizing process is done. A preparation of diastase made for the purpose is easily obtainable. The gruel should be salted and sweetened, if deemed necessary, by the addition of a rounded tablespoonful of Squibb's sugar of milk to each twenty-four ounces. In addition to the gruel, demulcent drinks, such as thin arrowroot water, are often grateful, and of some therapeutic value. Animal broths of mutton or chicken may be added to the gruel, also beef juice, carefully prepared from selected beef in teaspoonful doses. White of egg is now relegated to the long list of back numbers. It is insoluble, hard to digest, and often adds to the trouble already existing in the stomach and bowels.

As the condition of the bowels improves whey, made from fresh milk by the addition of rennet or essence of pepsin, sterilized by thorough boiling may be given, diluted one-half with arrowroot water or sterile water. Mild cases recover rapidly under such diet, and very often without any medicine other than the initial dose of calomel and castor oil.

In a certain proportion of cases bowel irrigation is of advantage. Every case does not require it, and in some cases it does positive harm. Where the movements are occurring every few minutes with tenesmus and pain, the rectum is already empty, and the introduction of the catheter acts as an irritant to the already inflamed mucous membrane of the bowel; there is increased straining, and very often rectal eversion follows the procedure. Irrigation is to be resorted to only in cases where there is no tenesmus, where the movements are infrequent, very offensive in character, and contain much mucus

The cases of very severe onset, with vomiting, fever, purging, and indications of acute ptomaine absorption, require most prompt and thorough treatment. Delay of even an hour may prove fatal. The stomach should be promptly washed, the bowel irrigated, and a two-drachm dose of castor oil administered. All food should be withheld and water given in teaspoonful doses every fifteen minutes. For the fever, cold packs, cold sponging, and, if the condition of the circulation does not contraindicate it, a rectal enema of a pint of water, at a temperature of 60° F., may be given. In collapse, a hot saline enema, at 100° F., is a valuable and ready stimulant.

The question of giving stimulants requires the physician's best judgment. The mild cases require none. Alcoholic stimulants are generally to be avoided. Whiskey and brandy are seldom retained, and usually serve only to further irritate the already inflamed gastric membrane. Hypodermics of strychnine, atropine, or digitalin may be administered if the case is sufficiently grave.

Warm fomentations over the abdomen, with a mild counterirritant, such as five minims of oil of mustard to the ounce of camphor liniment, applied to the skin, are grateful to the patient and help to relieve the pain.

In exceptional cases where the pain is so very severe that it becomes a factor in the general collapse, and the measures already indicated fail to relieve, a hypodermic of morphine may be resorted to, with proper caution.

The drugs to be used in the treatment of the diarrhœa are few. After the initial dose of castor oil or calomel—and the writer usually prefers the former—no medicine is required in the mildest cases. When the diarrhœa continues and there is mucus in the stools, with more or less tenesmus, subnitrate of bismuth with very small doses of Dover's powder is of service. Opium in any form is to be given with extreme care and in minute doses. To stop the diarrhœa suddenly is not our object. Opium will do this, but the condition of the child is not always improved thereby. The temperature rises suddenly, symptoms of ptomaine absorption become rapidly evident, delirium ensues, and the child will die if this plan of treatment is persisted in.

After the acute stage of the trouble has been passed and the movements no longer contain undigested curds or food, but are still loose, watery and frequent, a mild intestinal astringent is of value. Tannigen, alone or combined with subnitrate of bismuth, four grains of each, is a valuable drug at this time. It may be given preferably in powder mixed with a teaspoonful of cold water, every three hours.

The sick child must receive proper care and intelligent nursing. The clothes should be loose-fitting and everything done to add to the comfort of the little sufferer. It should be kept in as cool and dry an atmosphere as possible. In the country a shaded piazza is the most desirable place. Dampness and malarial influences are to be carefully avoided. Quiet is another very essential element. In extremely hot weather frequent bathing—two or even three times a day—is very beneficial.

Every possible source of irritation or annoyance to the child is to be sought for and relieved. Inflamed gums from erupting teeth, should be incised, chafed groins and excoriated buttocks should receive appropriate care, and no detail is too trivial to receive attention from the physician, nurse, or mother if the little patient is to make a rapid and unretarded recovery.

THE OPERATIVE TREATMENT OF HERNIA IN THE UMBILICAL REGION.

To accomplish a cure of an umbilical or a neutral hernia of any size, is often one of the most difficult things with which the surgeon is confronted, and many operative methods have been suggested which, in theory at least, promise a large proportion of success. The reasons for failure in a large majority of cases in which failure occurs are obvious and need not be enlarged upon, except that it is well to remember that in most instances the same conditions which produced the hernia in the first place will remain after operation, and that the abdominal wall will be in the same condition as before operation except at the immediate point of suture where it is at least temporarily stronger. For operative purposes, the neutral and umbilical hernias may be considered together, since they require the same treatment, and, size for size, give about the same results.

In the *Deutsche medicinische Wochenschrift* of May 15, 1902, Heinrich offers what appears to be a useful suggestion bearing upon this class of hernia, and claims a great theoretical advantage for the technique which he describes. The chief aim of operators has been to secure apposition, so broad and firm, that subsequent strain, which is inevitable, especially in a large abdomen, may not reproduce the hernia, but many failures to realize this favorable state of affairs have resulted, and attempts at improvement in technique are being made constantly. Heinrich's idea is to free a rather extensive area of the fascia of each rectus and to unite the resulting surfaces over as great a superficial extent as possible by means of silk sutures. The fascial sheath of the rectus should not be opened, since when the muscular tissue itself is freed from the confining sheath of the fascia, and is sutured to the muscular tissue of the other muscle, there is a great tendency for the fibers to separate longitudinally, and thus to cause serious weakness where strength had been expected. Whether it is necessary always to use silk sutures, is questionable, for the idea that the great strength of silk makes it a desirable suture material in cases of this class is certainly erroneous, since tension sufficient to exert a severe pull on the sutures will be enough to cause them to cut through the tissues to some extent, and thus to defeat the purpose of their insertion. Nonabsorbability is, perhaps, a good quality in a suture sometimes, but catgut can be so prepared that it will have this quality to as great an extent as is required, and there will be no future trouble from the necessity of removing knots, from which asepsis does not always protect us when we use silk.

It must be remembered that the firm union of fascial tissue requires a longer time than in the case of other more vascular structures, and for this reason after an operation for umbilical hernia it is necessary to keep the patient in the recumbent position for a considerable period, even though the wound gives all external appearances of being completely healed. Too early strain upon the new tissue which unites the fascial surfaces will certainly result in some stretching and yielding, and the chances of a recurrence of the hernia will be greater than if time is given for this new tissue to assume a firm fibrous character. As a rule, patients with hernia of this class are not good subjects for serious surgical work, since they almost always have the constitutional disabilities due to obesity, and, as we have indicated, the abdominal walls are objectionable surgically on account of their thinness and lack of firmness. However, many such patients must be operated upon, sometimes under the unfavorable accompaniment of strangulation, and improvements in technique are therefore welcome. The suggestion which we have been discussing seems useful, and good results ought to follow its adoption.

THE ETHICS OF CONSULTATIONS.

THE utility of consultations has often been questioned on the score that they mean little or nothing for the patient. The practitioner in a difficult case is supposed to need endorsement for his course, and he is said to obtain it in the unqualifiedly approving verdict of his counsellor. It is further claimed that the true ethics of the profession admit of no other alternative.

From the patient's standpoint this is true enough, and is as it should be in view of the necessity of preserving confidence in the medical attendant. The consultants have, on the other hand, every opportunity to differ in their private conference, but it is obviously unnecessary to do so in the presence of the family. Any disagreement that may exist as to diagnosis and treatment should be suitably adjusted before a conjoint verdict is rendered. If this course is impossible each one concerned should give a separate opinion and allow the patient or his friends either to choose what suits them best or seek other advice. Under no circumstances should such different views be offered until after the freest possible interchange of views in the secrecy of the consulting room.

We are called upon to make these statements in answer to the queries of a correspondent who complains of unfair treatment by a consultant who is claimed to have taken advantage of his position.

It is not necessary to detail the circumstances of the case further than to state that the difference of opinion was founded on a comparatively trivial matter of clinical history, and finally ended in the dismissal of the previous medical attendant.

The main difficulty arose in separate and exclusive examinations of the patient by the respective medical men, and in distinctly contrary conclusions likewise separately and independently expressed. The consultant coming from a distance was unable to have a formal consultation with the family physician on account of the latter's unexpected detention in another quarter, and in order to economize the time between trains hurriedly examined the patient, gave a snap and erroneous diagnosis—as was afterwards abundantly proven—and left irretrievable mischief of disagreement behind him,

It was a question of immediate operation or death founded on entirely false premises, and the alarm of the family and surprise of the regular attendant is not difficult to conjecture. The eminent gentleman who had come and gone was so plausible in his statements and so confirmed in his view that the patient was forced, in the absence of the family physician, to believe in him and acted accordingly. The operator was hurriedly summoned the day following, and with his special assistants and a trained nurse took entire charge of the case, virtually ignoring his professional brother, who was this time within waiting and convenient distance. When the latter declined subsequently to attend the patient and follow out the directions left with the family by the surgeon, he was quickly and indignantly dismissed by the hypnotized victim. The "plain doctor," as he calls himself, very pertinently asks if this was fair professional treatment at the hands of even a well-known expert.

The answer is obvious enough. It is just such circumstances as these and regretfully may it be said they are not very uncommon—that aim the death-blow at the utility of consultation from both sides of the equation and give the patient the coveted opportunity for ridiculing our science and misinterpreting our laudable intentions.

The duty of the interloper—for in a professional sense in the end he proved himself such—was either to confer directly with the other legitimate consultant or decline altogether to give the family any opinion. From any point of view it was highly unprofessional to do more, even under apparently the most stringent expediency, than address a private note to the absent physician and leave the subsequent details to be managed by him. The latter could then have seized an opportunity to discuss the point at issue and thus relieve himself of personal responsibility in the premises. Possibly also in the best interests of the patient he might have averted the death which was clearly hastened, if not directly occasioned, by the operation. Need we further point a moral to the disgraceful proceeding on the part of the meddling and discourteous expert?

Pure Food Laws.

At a time when there is so much agitation regarding the question of proper international ,national, and interstate food laws any specific data bearing upon the nature of adulterants in common use become alike interesting and instructive. Felix Paquin, Ph.G., chemist of the Memphis Board of Health, has a very suggestive article on this subject in the August issue of the *Memphis Medical Monthly*. The writer tells us that the following chemicals have been found in the various foods in common use:

"Boric acid and borates; salicylic acid and salicylates; benzoic acid and benzoates; fluorides, fluoborates, and fluosalicylates; phenols and phenol derivatives; sulphides and sulphites; formaldehyd; asaprol. Compounds and nostrums containing one or more of the above together with coloring agents—anilin dyes and carbonates. "Wine, beer, and milk frequently contain boric acid, salicylic acid, formalin, anilin dyes. Catsups nearly always contain salicylic acid and artificial coloring, sometimes benzoic acid. Jellies and jams, in most instances, contain benzoic acid, salicylic acid, anilin dye, and in the case of jellies a mineral acid to imitate the acidity of the fruit, which is in most instances entirely left out of its manufacture. Meats, especially sausages of all kinds, are preserved with sulphites, boric acid, salicylic acid, and anilin dyes. It is proper to mention that most baking powder bread, rolls, and biscuits contain a certain quantity of hydrate of alum or phosphate of alum. The cheaper alum baking powders are almost exclusively employed in their manufacture."

After this enumeration the auth discusses the effects of prolonged use of boric acid, the sulphites, salicylic acid, and formaldehyd. While admitting their preservative qualities, he very properly inveighs against their use in foods. Most of them interfere directly with the digestive process, some with urinary elimination, and others act as slow poisons. In fact, there appears to be no argument for their use except that of benefit to the manufacturer, who not only practises fraud upon the purchaser by adulteration, but oftentimes is enabled to place on the market foods which are in a state of decomposition at the time of their manufacture. The only remedy, according to Mr. Paquin, is the enactment of uniform laws throughout the country forbidding the use of all preservative ingredients not indicated on the package, making the inspection of food obligatory according to a fixed standard, and giving the preference to the home manufacture of the more perishable articles.

A Tuberculosis Squabble.

The Franco-Prussian War has been revived on a small, very small scale, the two and only combatants being Dr. Garnault of Paris and Dr. Koch of Berlin. The latter, it will be remembered, got himself much talked about last summer by springing upon the Tuberculosis Congress in London the views of various American observers (which he offered as his own without a word as to their true source), to the effect that bovine tuberculosis could not be transmitted to man. The love of notoriety being contagious, a number of men in different parts of the world quickly sprang into newspaper prominence by proclaiming themselves about to institute experiments to disprove Koch's assertion. Some of these scientists inoculated other persons, some more bravely inoculated themselves with tuberculous matter taken from cows. One of the latter was Dr. Garnault of Paris, who recently announced in a letter to the *Temps* that pieces of his skin around the site of the inoculation had been examined by Professor Tuffier at the Pasteur Institute, who had found giant cells characteristic of tubercle. The Berlin correspondent of the *Figaro* thereupon interviewed Dr. Koch, who said Garnault was playing to the gallery, and that his experiments were neither serious nor scientific. The real test, he said, would be to drink the milk of an infected cow, which, he added, would be harmless. Dr. Garnault is reported to be greatly incensed by the Berlin man's sneers, and says Koch is a poseur and a plagiarist, and he will prove him wrong if he has to die in doing so. He says that tuberculous milk is fatal to children, but harmless to adults, and that the experiment of drinking it would be ridiculous and unscientific at his age. The next battle will be fought in Vienna, for Garnault says he intends to publish a full account of his experiments, confounding Koch at the same time, in the *Neue Freie Presse* of that city. To the onlooker it is evident that both parties to this wordy war are in the right—in their characterizations of each other.

News of the Week.

Major Gorgas Still Saving Lives.—The United States Minister in Cuba has reported to the State Department a case of life saving by Major W. C. Gorgas of the Medical Department of the United States Army, who rescued a Cuban boy from drowning at Havana. Major Gorgas jumped into the water and rescued the boy just as he was sinking for the last time. A large crowd of Cubans, among whom were several policemen, were gathered at the water side watching the drowning boy, but none of them made any effort to save him. Dr. Gorgas had already saved a thousand or more lives, by his repression of the yellow-fever epidemic while he was at the head of the sanitary department in Havana.

The Value of Vaccination. Dr. D. W. Poor, in his recent report on the work of the Orange Smallpox Hospital, during the eight months it was in operation, adds to the mass of testimony regarding the protection afforded by vaccination. Among the eighty-six cases received there were nine deaths. Thirty-nine of the patients had never been vaccinated, and of these seven died; while among the forty-six vaccinated patients but two died, and these two had been vaccinated twenty or more years ago.

Crusade against Filthy Lucre.—Health Officer Friedrich of Cleveland has begun a crusade against the use of dirty money in that city, asserting that many cases of smallpox and other contagious diseases can be directly traced to its circulation. Many of the banks have agreed to gather in what they can of the worst-appearing of the paper money now in circulation and replace it with new bills.

A Queer Professor in Berlin.—Dr. Schweninger, Prince Bismarck's physician up to the time of the prince's death, has been appointed professor of the history of medicine at the University of Berlin. He is said to have reduced Bismarck's weight by cutting down his allowance of beer, and his grateful patient secured for him a sinecure on the faculty of the University. He has now been transferred from the chair of skin diseases to that of history. Medical professors at a number of German universities are said to be protesting against the appointment on the ground that Dr. Schweninger has never taught or written on the subject of medical history—but that is a small matter. The real grievance is that he has been made "ordinary" professor, whereas before he was merely an "extraordinary" one.

Mortality in New York City. The report of the Bureau of Records of the Health Department for the quarter ending June 30, 1902, states that there were in that time 17,173 deaths, 18,624 births, and 1,522 still-births. The number of deaths (17,173) in this quarter exceeded that of the corresponding quarter of the year 1901 by 558, this increase being due almost entirely to an increased number of deaths of children under five years of age; the greatest increase occurred among the deaths from diarrhœal diseases, there being 254 more deaths from these diseases in children under two years of age; there were 120 more deaths from measles and 195 more deaths from the acute respiratory diseases than in the corresponding quarter of last year; in addition to the foregoing an increase was noted in deaths from the following diseases, whooping cough, 117; cancer, 23; Bright's disease and nephritis, 53; suicides, 45. The noteworthy decreases were among the contagious and infectious diseases, to wit: smallpox, 31, scarlet fever, 170; diphtheria and croup, 38; influenza, 76; pulmonary tuberculosis, 130.

The Mississippi Valley Medical Association.—The twenty-eighth annual meeting of this association will be held on October 15, 16, and 17, at Kansas City, Mo., under the presidency of Dr. S. P. Collings of Hot Springs, Ark. The secretary is Dr. Henry Enos Tully of Louisville, and the chairman of the committee of arrangements is Dr. A. H. Cordier of Kansas City. The address in medicine will be delivered by Dr. Hugh T. Patrick of Chicago; the address in surgery, by Dr. George W. Crile of Cleveland, Ohio. The preliminary program contains tains the titles of thirty-nine papers promised for the meeting.

Medical Society of the Missouri Valley. The annual meeting of this association will be held on September 18, at Sioux City, Ia., under the presidency of Dr. Richard C. Moore. The Secretary is D. Charles Wood Fassett of St. Joseph, Mo.

First-Aid Instruction to Railway Employees.—The officers of the Chicago and Northwestern Railroad have ordered that all train men of the road are to receive instruction in first-aid to the injured. The details of the work are to be arranged by Dr. Owen, chief surgeon of the company. It has been estimated that 50 to 75 per cent. of the deaths which now occur from injuries received in railway wrecks would not occur provided the injured received skilful and intelligent aid at once. The value of the theory has appealed to the officials of the Northwestern. Every passenger and freight train will carry a medicine chest well stocked with all the materials which the surgeons think essential for the purposes. The employees who will receive instruction as to the best manner of using the supplies are engineers, firemen, conductors, and brakemen.

The Disposal of Rabid Dogs. The Board of Health has decided that hereafter all dogs that have bitten persons will be kept under observation for ten days in the laboratory at the foot of East Sixteenth street. When it is decided that they are not mad they will be returned to the owners, but if they are mad or have symptoms of hydrophobia they must be killed. A new section of the sanitary code makes it unlawful for the owners of such animals to take them out of the jurisdiction of the Board of Health.

The Status of Coroners' Physicians in New York City.—In connection with the application of Dr. Stephen E. Whitman for a writ of mandamus compelling his appointment as coroner's physician, a legal point was raised the other day which may put all of the Manhattan physicians out of office. Dr. Whitman was certified for the position on the ground that as former coroner's physician in Richmond he was in the preferred class. It was contended, however, that Dr. Otto E. Schulze, who heads the eligible list, should be appointed, and the coroners refused to appoint Dr. Whitman. In his argument in behalf of Dr. Schulze the lawyer argued that the Civil-Service Commission was compelled to certify his client's name, and that, as each coroner had a right to appoint his own physician, the section that took away this right on civil-service-law grounds was unconstitutional. Dr. Whitman's lawyer raised the point that such a contention meant that none of the Manhattan physicians held their positions legally. The question has not yet been decided.

A Hospital Interne Dismissed.—One of the internes of the Fordham Hospital was dismissed recently by the Board of Trustees for insubordination and discourtesy. The charges have not been made public, but it is understood that the young man refused to take orders from the medical board, and that he was discourteous to the supervising nurse. He was appointed to the position one year ago, since which time charges have been made against him twice. Recently, in the operating-room, he was ordered by the operator to remove the ether cone from the patient's face, but refused to obey. For this he was suspended for two weeks. A short time afterward the charge was that he had beaten a patient in the ambulance while on the way to the hospital. The charge was not substantiated, however, and was dropped.

Prince Edward Island Medical Society.—The annual meeting of this Society was held at Charlottetown on July 9. After the usual routine business was transacted, the following officers were elected for the ensuing year: *President*, Dr. F. F. Kelly, Charlottetown; *Vice-Presidents*, Drs. R. B. Shaw, Charlottetown; P. C. Murphy, Tignish, and G. A. C. MacIntosh, Murray River; *Treasurer*, Dr. P. Conroy, Charlottetown; *Secretary*, Dr. R. B. Shaw, Charlottetown.

The Health of the Troops in the Philippines.—Surgeon-General Forwood has made public the report of Lieut.-Col. P. F. Harvey, chief surgeon of the division of the Philippines, giving a detailed account of the health of the troops in the islands for the month ended on June 15. The report shows a considerable increase in percentage of sick as compared with that of the preceding month. The south Philippines sickness increased in quarters, station hospitals, and the department hospital, but, the report says, the reason for this cannot be indicated at this time. During the month covered by the report the total number of sick was 2,265, being 7 per cent. of the command present, 31,050, and during the same peroid there were seventy-nine deaths, including thirty-seven from cholera and one killed in action.

Columbian University.—Major Walter Reed of the Medical Department of the United States Army has been elected professor of general pathology at the Columbian University, Washington; Dr. Sterling Ruffin, professor of the practice of medicine; Drs. H. B. Deale and H. W. Hawkes, professors of clinical medicine, and Dr. Thomas A. Clayton, professor of materia medica and therapeutics; Dr. James Carroll, Acting Assistant Surgeon, U. S. A., has been appointed associate professor of pathology and bacteriology.

Shotgun Precocity.—According to the newspapers, a boy of seven years, living in Tennessee, shot and killed his brother of five the other day with a 22-caliber target gun, as the result of a dispute.

Antisepsis in Orange.—The Board of Health of Orange, N. J., is a progressive body, and many of its acts are worthy of imitation by other sanitary authorities. It has recently passed an ordinance requiring all barbers to wash brushes, combs, razors, cups, and other implements in boiling water before beginning business for the day. After finishing with each customer a barber, before using a razor again, must wash it in an antiseptic. The board has also adopted an ordinance requiring saloon and restaurant-keepers to wash in fresh water—not merely to rinse in a can of dirty fluid under the bar—every glass or drinking vessel before serving a drink. A penalty of $10 is fixed for every violation of either ordinance, and the board will have inspectors at work to see that the provisions are obeyed.

Smallpox in a General Hospital.—The Mountain Side Hospital of Montclair, N. J., which receives patients from several towns in the neighborhood, has been quarantined on account of the discovery of a case of smallpox in the medical ward. The patient was a servant from New York, who was taken ill soon after taking employment in Montclair, and the nature of her disease was not discovered until after she had been a day in the hospital.

Hospitals for Ironworkers.—It is announced that the officers of the American Steel and Wire Company have decided to establish a hospital for the treatment of employees on the grounds of each of the twenty-two plants of the company. The plans for the buildings, which will be as nearly uniform as conditions will permit, are being prepared by a Philadelphia architect, and the total cost to the company of buildings and equipment will not fall short of $300,000. The determination of the company to establish the hospitals was arrived at after a year's experiment with a temporary hospital at Allentown, Pa. It is calculated that within the next six months all the hospitals will be ready.

Cholera in China and Japan.—It is stated that the epidemic of cholera has spread from Manila and the ports of China to Japan. Up to the middle of July 231 cases and 142 deaths had been reported officially. Four cases occurred in Tokio. The number of cases in Fukuoka Ken was 121, of which ninety-three were fatal. At Tientsin up to July 11 the number of cases in the city was 1,049, of which 764 were fatal. The total in the northern section was 1,015 with 593 deaths. The epidemic is abating.

Prize Competition for the Erection of a Sanatorium for Tuberculosis in England.—The Advisory Committee appointed by the King in connection with the erection of a sanatorium for tuberculosis in England, announces that 180 essays were sent in in competition for the three prizes offered. The Committee was unanimous that the following essays were the best, and prizes have accordingly been awarded in the order mentioned: First prize to Dr. Arthur Latham of London, with whom is associated, as architect, Mr. William West of London. Second prize to Dr. F. J. Wethered of London, with whom are associated, as architects, Messrs. Law & Allen of London. Third prize to Dr. E. C. Morland of Croydon, with whom is associated, as architect, Mr. G. Morland of Corydon. Honorable mention was also made of essays of great excellence: Drs. P. S. Hichens of Northampton, Turban of Davos, Jane Walker of London, and J. P. Wills of Bexhill.

Professor Leopold Schenck, formerly of the University of Vienna, died at Schwanberg, Styria, on August 18. He was born in Hungary, August 23, 1840, and received his medical degree at the University of Vienna in 1865. He was appointed, in 1873, professor extraordinary of embryology and president of the Embryological Institute of the university, and in 1896 was made ordinary professor. Two years later he created a sensation by the announcement of his theory of sex determination. This was that the mother could ensure at will the sex of her child by means of a specially-arranged diet. The publication of this theory was the occasion of much adverse criticism, and Professor Schenck was forced to vacate his chair at the university in consequence. He always contended that his theory was scientifically correct, and that the opposition to it arose from ignorance and envy on the part of his colleagues.

Bequests to Philadelphia Hospitals.—By the will of the late Mary E. Jackson of Philadelphia a reversionary bequest of $6,000 is made to the Protestant Episcopal City Mission in trust for the Hospital for Diseases of the Lungs for the endowment of a free bed. The sum of $5,000 is bequeathed to the Pennsylvania Hospital for the endowment of a free bed, and the sum of $5,000 to the Prostestant Episcopal Hospital for the endowment of a free bed in the Harrison Memorial Annex for Incurable Patients, those afflicted with cancer to have precedence.

Obituary Notes.—Dr. Nicholas Williamson, Mayor of New Brunswick, N. J., from 1896 to 1902, died at his home in that city on August 15, of typhoid fever. He was fifty-four years of age. He began the study of medicine while paymaster in a local factory, and was graduated from the New York University Medical College in 1871. He also took the medical degree the following year from the College of Physicians and Surgeons in this city. He was prominent in public affairs as well as in his profession, and was largely instrumental in saving his city from bankruptcy at a time, in 1884, when its finances were at a very low ebb.

Dr. I. Renwick Glen died on August 5 at Plainfield, N. J., at the age of sixty-two years. He was a graduate of the medical department of the University of Pennsylvania. He was born in Fishkill, N. Y., but had lived in Pennsylvania and New Jersey most of his life.

Dr. Martin Luther Holbrook of this city, a well-known writer on popular medicine, died August 12, at the age of seventy-two years. He was born in Ohio and was brought up to farm labor, but a sharp attack of malaria turned his thoughts to medicine, and he was graduated in 1864 from the Hygeio-Therapeutic College, an institution which has since become extinct. He was associated for a time with Dr. Lewis in his propaganda of physical culture and hygiene. For thirty-four years he was editor of the *Herald of Health*, and was also for a period professor of hygiene at the Woman's Medical College in this city.

Dr. Thornsbury B. Yates of Grafton, W. Va., died at his home on the morning of August 7, aged forty-nine years and six months. The immediate cause of death was heart failure, superinduced by a long-standing spinal affection. He was a graduate of the University of Maryland of the class of 1878.

Perforation of the Membrana Tympani from Lightning Stroke.—H. McNaughton-Jones reports the case of an officer sitting on blankets in his tent and drinking from an iron cup, who suddenly, during a storm, found himself awaking, without any previous knowledge of having been injured. He was paralyzed except in his left arm, and various burned areas were scattered over his body. The hearing of the left ear was seriously affected, and when he was examined carefully a few days later, the perforations were discovered. The entire membrane was injected and of a deep red color. Two perforations were found, one in the posterior superior quadrant and the other below the umbo. Considerable tinnitus was present. Under the application of a weak silver-nitrate solution, protection of the ear with gauze, and occasional inflation, he made a gradual recovery.—*Journal of Laryngology.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING—THE MANCHESTER MEETING—EARL ROBERTS AT NETLEY—THE SMALLPOX EPIDEMIC—DENTAL HOSPITAL—MAJOR ROSS.

London, August 1, 1902.

The King's progress throughout the week has been steady, I may say rapid. The wound, now reduced to small dimensions, is closing satisfactorily, and his Majesty's general condition continues to be all that can be desired. The King can now walk the length of the pavilion deck of the royal yacht without assistance and quite easily. These facts are confirmed by the bulletin issued yesterday, and another will not be issued until Thursday in next week. Yesterday a second cruise of six hours was thoroughly enjoyed by the King, and it is expected that he will leave for London on Wednesday next. The Prince of Wales is expected to leave for town to-day. The surgeons feel no doubt that his Majesty will be able to go through the coronation ceremony on the 9th inst. without undue fatigue, a prognosis which your readers will have had opportunity to verify before this letter can be published.

Professional attention is directed to Manchester this week, where the B. M. A. is holding high revel amid its more serious discussions. Reproaches were lately leveled at it as nothing but an enormous picnic, and the hospitality of the north is doing its best to justify the jibe. Two garden parties in a day, dinners, a ladies' reception, soirée, a theatrical variety entertainment, a conversazione, an open-air fête, cricket matches—all these have been crowded in, and Saturday will be devoted entirely to excursions.

Manchester has certainly done its best to afford distractions. Nevertheless, some good discussions have been held, of which your special reporters will give you an account.

I hear that more than 1,500 members went to the meeting, which is, therefore, a success in point of numbers as well as of science and hospitality.

On Tuesday Earl Roberts went to Netley and distributed the prizes, after which he gave a most interesting address to the students. He said he understood their regret on leaving Netley, that this was the last session of the great school, but he thought there could be no doubt about London being the most suitable place for such a training school. No profession required more careful training than theirs, and in none was there greater necessity for constant study and research. In his own recollection, the advances in medicine and surgery were very remarkable. A few nights ago he had the honor of meeting Lord Lister, and he could not help telling him how deeply indebted to him they, as soldiers, were for his wonderful discoveries. Only those who could recollect what a field hospital was forty years ago could have any idea of what had been accomplished by the introduction of antiseptics.

They were about to enter on the active work of a noble profession, and the Indian service offered in many and various directions opportunities for men of ability and industry to come to the front and achieve success and distinction His lordship then mentioned some of the medical officers who had distinguished themselves in India in various sciences during the last 200 years, to show them the unique prospects before them, and hoped all would bring their best energies to maintain and increase the splendid reputation and grand traditions of the service to which they belonged. He commended the natives of India to their special care, and advised them to lose no time in learning their language and cultivating their friendship. There were many able natives in the lower ranks of their profession from whom they would obtain valuable assistance if they treated them with the kindness and courtesy due them, and which they would thoroughly appreciate. He wished them all prosperity in India.

The Asylums' Board had a long discussion recently respecting the epidemic of smallpox, which was regarded as stamped out. But the danger of recrudescence in the autumn will not be forgotten. The Board decided to have a motor ambulance constructed, at a cost of £1.000, for the conveyance of patients. There was a further proposal to have a midway ambulance station, but this was rejected. The charge levied on ratepayers for maintenance of smallpox patients in the Board's hospitals has been 1s. 8¾d. per head per day. The chairman of the Hospitals' Committee seemed very satisfied with the way the epidemie was met and "stamped out," the admissions becoming fewer week by week. The Board adjourned until October without publishing the statistical statement I hear that it contained proof that the interim report issued in January placed the mortality too high—24 per cent.—and that the corrected figure is 17 per cent. During the last fortnight there have been 115 admissions, 276 discharges, and 16 deaths. The number remaining under treatment on July 26 was 372.

Mr. Morton Smale, Dean of the Royal Dental Hospital, presided at the distribution of prizes. This being the first gathering since the King conferred the title of Royal on the hospital, Mr. Smale proposed, before going on with the distribution, to send a message expressing heartfelt thankfulness for his Majesty's recovery and gratitude for the honor conferred. This proposal was adopted with enthusiasm, and the prizes were then distributed by Sir A. Rücker, who commended to the students the London University, which he believed would become one of the most marvellous institutions in the world.

Major Ronald Ross will proceed to Ismailia in September to assist the Suez Canal Company to cope with malaria. Major Ross continues his connection with the Liverpool School of Tropical Medicine. He did not accept the offer to come to the Jenner Institute.

The new Thames Tunnel is completed, and for two days is to be opened at a small charge, for the benefit of the Seamen's and Poplar Hospitals. Afterward it will be a free means of communication between the two sides of the river.

DIET, DRUGS, AND DIAGNOSIS IN TYPHOID FEVER.

To the Editor of the Medical Record

Sir: An analysis of Dr. Charles H. Lewis's article with the title given above, which appeared in the Medical Record for August 2, 1902, brings out some curious points.

Of the ninety cases reported in the article six ended fatally, and it was apparent when they were first seen that they would so terminate, in spite of any care or treatment. So that under Dr. Lewis's treatment the mortality was *nil*, if the patient was seen before he was in extremis. The doctor is to be congratulated on this happy outcome, and yet he says: "The physician who never loses a case is instinctively set down as a man who never has one, or who does have a treacherous memory."

The first and most important result to be striven for by the physician is the ultimate and complete recovery of his patient, but this is not the only object he should have in view. If the patient is a producer, every day he is sick is a loss to himself and to the community, and it is the duty of his physician not only to cure him, but to cure him as quickly as possible. Of Dr. Lewis's ninety cases six died, and in one, No. 76, the date of onset is not given. The eighty-three remaining cases were sick an average of over sixty-two days each, and were under treatment an average of over fifty-three days each. Of these eighty-three cases four were complicated, one with double parotitis, one with intestinal hemorrhages, and two by relapses. This leaves seventy-nine cases of ordinary typhoid fever that were sick an average of over sixty days each, and under treatment an average of over fifty-one days each. Of these seventy-nine cases thirty-two were seen on or before the eighth day. This makes thirty-two cases of simple, uncomplicated typhoid fever, first seen on or before the eighth day, in which the average duration of sickness was over sixty-four days, and the average time under treatment over fifty-eight days. Cases 66, 67, and 68 were under observation from seven to fourteen days before there were any symptoms of the disease, and were under treatment from the very beginning of the attack, and yet they were sick on an average of over eighty-five days each. These three were presumably strong children, aged five, three, and seven years, respectively. The question is why were they sick so long? When a fairly strong and healthy person is attacked with typhoid fever, is seen early, given good nursing, and persuaded to drink large quantities of sterile or acidulated water; when he is kept quiet in bed, and the bowels are kept open; and when the disease runs an uncomplicated course, and no other treatment is used, he should be able to resume his ordinary occupation inside of forty days, as an average. When this is not the rule, something is wrong, generally the treatment. It is fair to suspect that a treatment that results in such patients being sick an average of over sixty-four days each, retards rather than hastens their recovery. It is not possible to say positively that there is anything in Dr. Lewis's treatment that would have this effect, but it is open to criticism in some particulars. The large, iritial dose of calomel, generally followed by a saline, has the approval, I think, of everyone who has tried it; but the small continued doses of calomel have not proved of use in the hands of many careful observers. A large dose of calomel not only empties the intestines and the gall-bladder, but it also has considerable effect as an intestinal antiseptic. One-half a grain of calomel, twice a day, has no local action on the intestine, and it is doubtful if it increases the secretion of bile; that it had no effect whatever in Dr. Lewis's cases (except to cause stomatitis), is apparent.

The slow recovery of these patients was due, I believe, to the manner of feeding them. I have come to think in the last few years that milk is one of the worst possible foods in typhoid fever. The undigested curds pass into the intestine, where they ferment and putrefy, thus prolonging and intensifying the irritation already present. Toast I also believe to be a dangerous food during and for a short time after typhoid fever. This was pointed out over fifteen years ago by Dr. E. W. Hedges of Plainfield, N. J., inan article in the Medical Record for January 29, 1887, page 136, where he cites three cases of relapse in typhoid fever, apparently caused by eating toast. In the cases under consideration the toast was not given until late in the disease, and I am unable to see, from the tables given, that it did any harm; nevertheless, I believe it to be too dangerous a food to use in such cases. In an article by me in the Medical Record for June 30, 1900, entitled "The Treatment of Typhoid Fever," will be found a description of a method of treatment; and in the Medical Record for September 30, 1893, under the head of "Camphorated Carbolic Acid," will be found a description of the remedy. The main points in my plan of treatment are, the use of carbolated camphor as an intestinal antiseptic, a blood antiseptic, and a stimulant to the abdominal nervous system; an initial dose of from ten to thirty grains of calomel, and occasional doses of five or more grains throughout the course; a tablet of aloin gr. $\frac{1}{8}$ and podophyllin gr. $\frac{1}{8}$ every day or second day (except when the calomel is given), to increase the section of bile, and to keep the gut empty; strong feeding, by giving such food as will be absorbed from the stomach without passing on to the intestine, and by giving it in small doses, frequently repeated; large draughts of sterile water; and absolute rest. The carbolated camphor is simply gum camphor three parts and crystals of carbolic acid one part, allowed to liquefy. There should always be visible camphor present in this liquid, in order that the carbolic acid be kept super-saturated. It should be given in ten-minim doses, in a capsule, every two hours, until the kidneys or heart show signs of irritation, when the interval between doses may be increased. For food I depend almost entirely on dissolved beef, made after Weir Mitchell's formula; and egg albumen stirred into cold water, and acidulated either with lemon juice, or hydrochloric acid. Sometimes I use liquid peptonoids as a change.

Under this treatment I have not lost a case in fifteen years, and I have seen a good many, and my memory is still in good working order.

Moreover, and this is the point that I wish to emphasize, if I see a case before the eighth day, and there are no complications, that man is back at his work before the end of the fifth week. When I see the case early there are almost never any complications. This is not the old carbolic-acid treatment; it would be more nearly correct to call it the camphor treatment. But the good effects are undoubtedly due to the combination of the two drugs.

D. E. English, M.D.

Milburn, N. J.

Epilepsy in Its Relation to Crime.—William P. Spratling places the number of epileptics who become permanently insane in a legal sense—that is, who are continuously unable to distinguish between right and wrong—at not less than 15 to 20 per cent. The epileptic subject to prolonged periods of mental disturbance and not continuously insane, may be in a subconscious state, lasting from a few minutes to several days after cessation of the fit. His mind is a blank, his actions go on uninterruptedly, and should he commit a crime while in this state he ought not to be held responsible for it, since he could not have had criminal intent. Aside from the epileptic's inability to distinguish between right and wrong when under the influence of a seizure, we ought to remember that inhibition in most cases is also impaired or destroyed; a fact that seems to escape consideration in establishing responsibility in epilepsy in this country. Judge Somerville held that the true test of responsibility in cases of insanity is the power to refrain from doing the act—in other words, whether the alleged evil doer acted under duress of disease which may have impaired or destroyed his powers of inhibition. The application of a similar test in establishing responsibility in epilepsy would seem especially fitting and just.—*Journal of Nervous and Mental Disease.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, August 14, 1902.

A Consideration of Uræmia. William H. Robey, Jr., reports several cases, a study of which shows that the patient who presents all the signs of marked degeneration of the kidneys and whose daily excretions is far below normal, does not necessarily die of acute uræmia, and need not even have any uræmic symptoms, while one in whom the insufficiency is apparently very slight, may suddenly develop uræmia, although before and during the attack the kidneys seem to be doing their work, and at the autopsy are found to be no more degenerated than those of persons dying of some other condition In past years the kidneys have been considered adequate if they were secreting a fair amount of the solid constituents of the urine. These cases clearly show that we must radically revise our ideas of renal insufficiency, and must learn to recognize new elements in urine or blood before we can justly make a prognosis in any case of chronic nephritis, no matter how favorable the condition may appear when measured by our present standard.

Journal of the American Medical Association, August 16, 1902.

Sodium Glycocholate in Diseases of the Liver.—T. W. Keown concludes that the indiscriminate use of glycocholate of sodium is to be avoided; it is not suited to all cases, and although there are no contraindications to its use, yet good results are to be expected only in those cases of gallstone formation of so-called torpid liver found in certain diseases, such as alcoholism, drug habits, melancholia and its congeners, constipation, chronic malaria, etc. It also materially aids the digestion of fats, and may prove a useful adjunct in wasting diseases of all kinds.

The Present State of Our Knowledge Concerning So-Called Partial or Graduated Tenotomies and the Heterophorias. J. Elliott Colburn states that the operation for a few years following the publication of the first reports of cases by Stevens, Ranney, Standish, and many others, was employed for the cure or relief of all sorts of conditions, and of necessity there was a reaction, but, through the careful and legitimate employment of the procedure in properly-selected cases, it has taken its place as second only to refraction in relieving certain forms of eye-strain, and is practised by conservative ophthalmologists. The author usually gives his patient the choice between (1) a six-months' course of ocular gymnastics and general tonic treatment, doing but a limited amount of close work, with the possible result of an improved if not corrected muscle balance, with a reasonable hope, if the general health remains good and the muscles are not overtaxed, that there will be no relapse; and (2) a two to six weeks' treatment, undergoing the development of the total error and its correction by operations, with the establishment of an orthophoric condition.

Medical News, August 16, 1902.

The Etiology of Typhoid Fever.—Wm. Egbert Robertson, from a study of the literature on this subject, concludes that the all-important factor in the causation of typhoid fever is the bacillus, which, for some unknown reason, manifests a peculiar tendency to appear among us at regular intervals; that anything which affords an opportunity for its entrance into an individual predisposes to an attack of the fever; and that every case may serve as a source of infection to others, but, unlike the other exanthemata, only by the use of contaminated food or drink, or water used for various household needs. He refers to Traube, who reported one case only of direct infection, which occurred in a hospital patient, into whose rectum a thermometer had been placed just after it had been used on a patient ill with typhoid fever.

A Case of Isolated Neuritis Complicating Typhoid Fever.—Charles J. Aldrich reports the case of a laborer, thirty-eight years of age, who, during convalescence from a grave relapse of typhoid fever, developed a neuritis of the left external popliteal and left ulnar nerves. Both legs and feet were œdematous and painful, and there was some numbness and tingling in the distribution of the above-mentioned nerves. On the left ulna and right tibia some hard, tender nodes, evidently periosteal tumefactions, were discovered. The patient also complained of much pain in the neighborhood of the sternum opposite the fourth costal insertion, at which point there was found an indurated swelling, caused, in the author's opinion, by necrosis. Its operative treatment was refused by the patient. There was a left foot-drop; the area of anæsthesia corresponded to the integumental distribution of the left external popliteal. The left hand had a weak grasp, and pain and touch sensation were absent in the distribution of the left ulnar nerve. Attention is called to the observation that the external popliteal or peroneal nerves, as well as the ulnars, seem to be especially vulnerable to the action of the various toxins of acute infectious disease.

New York Medical Journal, August 16, 1902.

Consideration of the Aortic Aneurysm. James Dudley Morgan considers the location and frequency of aortic aneurysm, its pathogeny, and principal symptoms. Quoting Sir William Jenner's injunction: "Suspect anything else but aneurysm in examining a pulsating tumor of the abdomen," he points out the great similitude with which the abodminal aorta of a neurasthenic may take on an aneurysmal feature.

A Summer in Wood's Holl.—Beaman Douglass, believing that a paper on his experiences at Wood's Holl might serve to open a new channel for thought, even though it might not contribute any actual scientific facts to the medical profession, describes the life of the numerous students at that resort, and gives an account of the various courses of lectures and laboratory instruction given in zoology, botany, physiology, and embryology, most of which are of great interest to the physician.

Tenotomy and Myotomy, with Reports of Eight Illustrative Cases.—Prescott Le Breton discusses at length the subject of tenotomy and myotomy and their indications. In cerebral paralysis division of the spastic muscles has greatly simplified the treatment. The tendo Achillis, plantar fascia, tibials, hamstrings, thigh adductors, and various tendons of the arm and hand may all require cutting, depanding upon where the spasticity and incoordination exists. Traction is of no service, as deformity recurs immediately. In infantile spinal paralysis flexion at the hip, except in very severe instances, is best treated by traction in bed, or partial tenotomy followed by traction, as tenotomy in this region is rather formidable. At the knee mild flexion may yield to bandaging or plaster-of-paris splints, but the hamstrings are ordinarily severed and suitable apparatus is provided. Deformities of the feet require tenotomy and immobilization in the corrected, not overcorrected, position. Other cases in which tenotomy may be of service are: Friedreich's ataxia; post-typhoidal contractures; pseudo-hypertrophic muscular paralysis in its later stages; long-standing hysterical contractures in which structural changes have taken place in the muscles; flexion deformity of the hip and knee at an advanced period of the lesion; severe cases of psoas-contraction of Pott's disease; congenital and acute spastic torticollis; clubfoot and clubhand. The cavus existing in cases of paralytic talipes equinus should be corrected by forcible reduction and section of resisting bands of plantar fascia. For the relief of congenital elevation of the scapula, the trapezius, rhomboids, levator anguli scapulæ, and part of the serratus magnus have been divided with successful results.

American Medicine, August 16, 1902.

Remarks on the Hæmatology of Rheumatism. A. M. Davis gives a very summary review of the etiology of this disease (omitting most of the more recent investigations) and quotes the various findings of clinicians as regards the blood as a whole, the red cells, leucocytes, and æmoglobin. For determining the total acidity of the blood he recommends Lowy's method as more practical than that of Landois-Jaksch. Although these tests are of practically no clinical significance, as they do not help to arrive at any definite conclusion concerning the real condition of the blood, the author hopes that laboratory methods will be devised in the near future by means of which definite and reliable analyses of the free and combined acids can be made, and that their detection may tend to solve the problem of the specific etiology of rheumatism.

Arthrodesis of the Ankle for Infantile Paralysis.—John Dane makes a plea for early operation upon the following grounds: (1) By avoiding the use of costly apparatus for a period of years a considerable saving in money and a still greater saving in trouble is effected for the parents as well as the child; (2) At an early stage in the trouble (*i. e.* about a year after the onset) the bones are relatively normal, both as regards their shapes and their mutual articulations; nor are there marked malpositions of the foot as a whole, which so often have to be overcome in operations at a later stage; (3) The tissues are then in a period of great plastic activity, when repair is both quicker and more perfect than in the older child. Cartilage is being changed into bone all through the foot, and we have less fear of a failure to secure bony union at the site of operation; (4) When at an early age the foot is secured in a relatively normal position the statics of the lower limb are not so much disturbed, and growth goes on under more nearly normal conditions than can be possible when there is a constantly increasing tendency to the transmission of weight along abnormal lines; (5) By avoiding mechanical support the unaffected and partially paralyzed muscles are not subjected to the injury inseparable from the use of constricting bands and straps. They have, in consequence, a freer blood supply and develop more rapidly

Recurrent Vomiting.—Charles W. Larned gives the histories of two cases representing typical instances of the affection in children aged four and five years, respectively. The vomiting, having once begun, was almost incessant in both children, the second child having had sixty-one seizures in the course of twenty-four hours; in both cases, toward the end of the attack, the vomitus contained more or less blood and bile. Constipation during the attacks was most obstinate in both children, the stools when passed being decidedly light in color and very offensive. During the early stage, in both instances, the urine was very scanty, high-colored, but showed neither albumin nor casts. Toward the end of the attacks in the second case a trace of albumin and a few granular casts were often found; this condition cleared up rapidly, however, after convalescence had set in. The abdomen became scaphoid in both instances after vomiting had lasted for some hours; in neither case was abdominal pain complained of, and only slight uneasiness was elicited on palpation. The temperature did not exceed 100° F in either child. There was intense thirst, but desire for food was absolutely wanting, although both children became ravenous as soon as the vomiting had subsided. The character and frequency of the pulse and respiration differed in the two cases. The duration of the attacks was from one to four days in both children. In neither child was there the slightest regularity as to the time of recurrence. The author discusses the clinical manifestations, etiology, pathology, prognosis, and treatment of the disease.

Philadelphia Medical Journal, August 16, 1902.

The Infectious Origin of Purpura Hemorrhagica.—A. W. Schram and W. H. Rubovits report a fatal case of purpura hemorrhagica, in which the degenerative tissue changes found post mortem, especially those in the blood vessels, lungs and kidneys, the uniformly enlarged lymphatic glands and spleen, the intestinal changes, the altered blood, and, above all, the circulation of microorganisms in the blood, were characteristic in every respect of septicæmia. The pathological findings of purpura hemorrhagica have revealed nothing which may be interpreted as the characteristic morbid changes of an independent affection; of a disease *per se*. None of the conditions found either clinically or pathologically, is sufficient evidence to accord to the so-called primary or idiopathic purpura the dignity of an independent affection, but they are rather the manifestations of a morbific influence, of which the purpura is a prominent clinical sign. From a pathological standpoint at least, purpura hemorrhagica must be regarded as one of the manifestations of septicæmia.

Malarial Fever Mistaken and Treated for Thermic Fever—J. Valentine Levi and Joseph M. Asher report three cases, which were brought to the University of Pennsylvania Hospital during the extreme hot spell in July of last year, with a large number of genuine cases of thermic fever. Tubbing produced little or no effect, and when the patients were well enough to be questioned, two of them gave a history of malaria. Examination of the blood showed the plasmodium in two of the cases, including the one which gave no malarial history; in the third no plasmodia were found, but excessive pigmentation was present. Improvement occurred under quinine treatment in all. In the "Twentieth Century Practice of Medicine," it says: "Sunstroke may simulate an attack of pernicious fever in malarial climates, and in summer when it attacks men mostly in the field." Marchiafava and Bignami also state that there are cases of malarial fever complicated with sunstroke. Even if this be the case, the value of the knowledge that malaria is present is self-evident.

The Lancet, August 9, 1902.

A Peculiar Case of Scarlatina Hæmorrhagica.—V. C. de Boinville records the case of a boy, four and a half years of age, who had an attack of scarlet fever that presented nothing unusual. The day after the temperature had fallen to normal, however, and, just as desquamation was setting in, bleeding from the anterior nares commenced and small hemorrhagic spots appeared on the anterior aspect of the scalp and in the neighborhood of the knee-joints. Subsequently an eczematous rash broke out on the buttocks, and the spots thus formed bled on the slightest friction. The patient became generally feeble, the temperature rose to 103° F, and death ensued in a state of collapse. The author asks whether it can be that nature had, as it were, surpassed herself in her process of healing, that the antitoxins had become excessive, and that a "reactionary antitoxæmia," if one may use such a term, had set in. Or can it be that, after the supposed toxins had been sufficiently eliminated, to permit of a fall of temperature and partial recovery, a fresh supply of toxins hitherto combined with other material, or otherwise rendered inert, had suddenly become let loose in the blood and set up a secondary toxæmia?

Myoma of the Vagina.—W. Roger Williams discusses the pathology, diagnosis, and treatment of this rare form of vaginal tumor. As in the case of their uterine congeners, the precise structure of the so-called vaginal fibroids has been much debated; the report of cases rarely enable us to determine with certainty whether we have to do with myomatous, fibromyomatous, or merely with fibromatous formations. Probably further investigation will show that nearly all vaginal "fibroids" are myomatous *ab origine*. They differ from their uterine congeners in their comparative rarity, and in that they are nearly always solitary. They increase slowly, but seldom attain a large size. A considerable proportion of individuals affected with these tumors are single, an among the married the ratio of sterility is in excess of the normal. Menorrhagia or other menstrual derangement rarely occurs. Myomata of any size, especially when they interfere with natural functions or present signs of septic infection—inflammation, œdema, sloughing, etc.—should be removed. If the tumors are polypoid and the pedicle is of no great thickness, the latter should be transfixed, ligated in two places, and divided between the ligatures. In all other cases enucleation is the best treatment.

Verbal Obsessions.—James Shaw defines verbal obsessions as those in which isolated words—mostly obscene or blasphemous—constitute the morbid besetment. They should be distinguished from coprolalia, obscene speech; from the blasphematory mania of Verga, which this observer describes as a special variety of obsession taking the form of oaths, blasphemies, or indecent utterances; and from the onomatomania of Charcot and Magnan, in which a word cannot be recollected without a painful searching of the memory, or a word or phrase is ever present in consciousness and must be emitted at intervals, its utterance being repressed for a short space only at the cost of extreme and constantly increasing mental pain. In the two cases he records the besetting words were never uttered. The words differed from psychical or psychomotor hallucinations, in that they were never spoken of as "voices in the head," nor as "voices" at all. Verbal obsessions may constitute the leading feature of a sort of obsessional aberration, as in one of the cases, or an early symptom of a form of insanity, an obsessional melancholia. The other case exemplifies the induction of obsessional melancholia by verbal obsessions. The prognosis as to mental recovery is much less favorable in the aberration almost purely obsessional than in the seemingly more formidable obsessional melancholia with its blurring of consciousness, greater mental pain, and diminution of self-control, difficulty of inducing fatigue, and its presentation of a distinct fixed idea or so-called faith-delusion of having committed an unpardonable sin.

The Diagnosis and Treatment of Malignant Stricture of the Œsophagus.—Charters J. Symonds considers a few of the early symptoms and the treatment of this disease, which is not infrequently treated for dyspepsia. He summarizes the diagnosis as follows: (1) Among early symptoms we may have so-called dyspepsia, nausea, and repulsion for food; pain alone when the central district is affected; (2) The passage of a bougie is the only way to clear up the case, and its employment need not be feared; (3) Extraœsophageal disease rarely gives rise to serious dysphagia; (4) Spasmodic obstruction, apart from the hysterical form, has always, when pronounced, an organic cause, and this would be better called intermittent dysphagia; (5) With regard to the three special districts, it may be said (*a*) that all organic obstruction in the upper third is malignant and has a special tendency to cicatrize; (*b*) that in the center half of the gullet a sarcoma or a myoma, both rare diseases, may cause fatal obstruction, and here also a pouch may give rise to difficulty in diagnosis, but can generally be excluded; and (*c*) that in the lower end alone does simple stenosis occur, and here there may be difficulty in distinguishing it from cancer of the stomach causing great reduction of the cavity (leather-bottle stomach); (6) Finally, in estimating the extent of the disease, the special value of the steel bulb is noted, and also the use of the coudé bougie in obstruction at the lower end. The general question of treatment is put in the following way as applying to all cases: (1) While the patient can swallow fluids and semi-solids, and while a bougie can be passed and plenty of nourishment taken, he may be left alone so long as (*a*) he can swallow well, or (*b*) a small bougie, No. 12 catheter gauge, can be passed; (2) If the dysphagia increases, even though a bougie can be passed, then a tube must be inserted or gastrostomy must be performed. These conditions are seen in the soft fungating forms; (3) If a bougie cannot be passed or goes with difficulty, then the same course must be followed, as we know that complete closure may occur at any time; (4) If both conditions arise, *i. e.* the patient cannot swallow and a bougie cannot be passed, then immediate mechanical treatment is required.

Deutsche Medicinische Wochenschrift, July 24, 1902.

Formation of a Fistula between the Liver and Lung.—Eschenhagen's patient had suffered for several years with cholelithiasis. At the time of the initial observation a complicating purulent cholangitis had developed, and the general condition was extremely bad. The patient rapidly passed into a comatose condition, and physical signs of a right-sided pleurisy appeared. An examination of the blood failed to show the presence of any leucocytosis. The liver, which had been considerably increased in size, returned practically to its normal proportions, and the coma gradually disappeared. Shortly thereafter the expectoration suddenly became yellow-colored, and upon examination was found to contain the various elements of bile. The pleurisy subsided and the general condition greatly improved. There then followed a period of about four weeks during which there were frequent attacks of bile-expectoration. Ascites developed, the cardiac action became greatly impaired, and death took place under appearances of marked asthenia. At the autopsy it was discovered that the infectious cholangitis had given rise to multiple liver abscesses, one of which had broken through into a bronchus of the right long, thereby causing gangrene and pleurisy in the territory involved and producing the bile-expectoration above noted. The case is of interest because of the great rarity of thorax-liver fistulæ, and also because of the absence of a leucocytosis, although the process from the beginning must have been septic in nature.

A Rare Case of Perforation Peritonitis.—Paul Hilbert reports a case of peritonitis due to a perforating ulcer of one of the diverticulæ of the sigmoid flexure. The patient was a male, thirty-seven years of age, and had suffered with pains in the right hypochondrium, together with dyspnœa, cough and expectoration, for about six months previous to his coming under observation. During the latter portion of this time there had developed an abundant ascites and a moderate œdema of the lower extremities. Upon physical examination of the chest the lungs were found normal, but a marked cardiac insufficiency was detected and was held responsible for the clinical picture. The ascitic fluid was withdrawn by puncture, and upon microscopic examination was found to contain numerous erythrocytes and pus corpuscles. Within a few hours after the withdrawal of the fluid the temperature rose to 38.9°C., and characteristic symptoms of peritonitis appeared. These increased in severity, and death took place within three days. Upon autopsy the perforated ulcer above noted, was found, and the cause of the peritonitis thus detected. The case is of interest in that a review of the literature shows that perforating ulcers of the intestinal tract are extremely rare in the sigmoid flexure; and, furthermore, because of the peculiar clinical history, the symptoms of peritonitis not developing until the ascitic fluid had been withdrawn, in spite of the fact that the examination of this fluid demonstrated that infection of the same was present previous to the puncture. It seems probable that the absence of peritoneal symptoms was due to the presence of the fluid in the peritoneal cavity, which separated the layers of the peritoneum and thus prevented the characteristic local symptoms so characteristic of this disease.

Berliner klinische Wochenschrift, July 28, 1902.

Lupus Erythematodes.—Eugen Holländer takes sides with those who hold that lupus erythematodes is in no way tubercular in nature. There are many facts which may be advanced in support of this opinion, but that which carries the most weight is the result obtained by a cauterization of the lesions of this disease. Experience has shown that this form of lupus cannot be cured by cauterization, no matter how thoroughly and carefully this may be done. Surely, if the lesions were caused by the bacillus tuberculosus, means which destroy this microorganism should be effective in the treatment of the disease. Holländer reports the successful treatment of a large number of cases by the internal administration of quinine combined with the local application of the tincture of iodine. The quinine is given in doses of .5 grams, three times a day, and within five to ten minutes after each dose the iodine is applied. This treatment is continued on each of five or six successive days, and then intermitted for a like period. The number of treatments necessary varies with individual cases, but. as a rule, does not exceed three or four of the periods above described. The exact manner in which the cure is brought about by this treatment is not entirely clear, but since it seems certain that the disease, primarily, is an affection of the cutaneous glands, it is reasonable to suppose that the drugs mentioned exert an influence upon the vessels of these glands, and thereby favor a restitution of their normal functions.

Myelogenous Changes in the Spleen and Lymph Glands. Hans Hirschfeld reports the post-mortem examination of many cases of scarlet fever, diphtheria, erysipelas, sepsis pneumonia, peritonitis, purulent meningitis, and pulmonary phthisis, with a view to ascertaining the varieties of leucocytes present in the spleen and lymph glands. It was found that in many cases these structures contained a large number of polymorphonuclear neutrophilic leucocytes and neutrophilic myelocytes. Eosinophilic myelocytes were rarely found. Normoblasts were frequently encountered. The neutrophilic myelocytes were more abundant in the spleen than in the lymph glands. The question now arises as to whether the myelocytes in these cases originate in the spleen and lymph glands or whether they are carried thither from the bone marrow by the blood. It seems certain that the former is the case, since when the myelocytes were found in the spleen and lymph glands it had never been possible to demonstrate their presence in the peripheral blood during life, as would be expected provided that they had been present in the general blood current. If therefore it is true that in these instances myelocytes originate in the spleen and lymph glands, Ehrlich's view that they are formed only in the bone marrow is false. Hirschfeld in opposition to Ehrlich has maintained for years that myelocytes are not of independent origin, but that they are formed from the lymphocytes. Until recently it has seemed certain that this transformation took place only in the bone marrow. The observations here recorded, however, show that under cercertain conditions the same process may go on in the lymphoid structures, for if it is granted that myelocytes are ever formed in the spleen and lymph glands, in such cases they could originate in no other manner than from lymphocytes, and a similar origin in the bone marrow is to be naturally supposed. The explanation of the myelogenous changes in the spleen and lymph glands in certain cases of infectious diseases would seem to rest upon the leucocytosis necessary for protection. In such the bone marrow is not able to produce the necessary number of leucocytes (phagocytes) and the formation of the phagocytes is transferred in a certain measure to the structures above named.

Münchener medicinische Wochenschrift, July 29, 1902.

Spinal Reflexes in Hysteria.—Steiner reports a case of hysteria which shows an unusual relation of the reflexes. It has been generally taught that in this disease the tendon reflexes are maintained while the cutaneous reflexes in the involved territory are reduced or absent. It is evident, however, that this relation does not always hold true. The case under consideration was without question purely hysterical in nature, and was kept under observation for more than two years. In the beginning the tendon reflexes were preserved and the cutaneous were absent. Later, however, this relation was reversed. Subsequently the tendon reflexes returned and the cutaneous vanished. This case shows that an absence of the tendon reflexes does not not necessarily mean that organic lesions are present.

Ulcer of the Stomach.—Agéron considers the various points in the diagnosis of ulcer of the stomach. Great importance in this respect is to be attached to disturbances in the motor functions of this organ. It is certain that in many instances of this disease in which the well-known classical symptoms are absent an early diagnosis may be made by the help of accurate observations upon the motility of the stomach. It is thought by many that a disordered motility does not occur until the ulcer is far advanced and has given rise to stenosis or other marked anatomical lesions. Sufficiently careful observations, however, will show that this is very far from being true. The motility is best determined by means of the test meal. If within two hours after the ingestion of such a meal the stomach is not entirely empty it may be regarded as certain that the normal motility of the organ is impaired. Such an impairment is never met with in cases of hysteria or so-called nervous dyspepsia. Two points in the treatment require especial emphasis. First the necessity of continued rest in the horizontal position and, second, the influence of the subgallate of bismuth upon the ulcerative lesions. The bismuth is best administered suspended in oil. Ten grains should be thus given three times a day, the stomach having been previously cleansed with a warm boracic-acid solution.

Clinical Significance of Retroflexed Uterus.—A Theilhaber disagrees with Wormser, who thinks that during the second and third months of pregnancy the retroflexed uterus should be manually replaced and supported by a pessary. While this may be necessary in places where the displaced uterus is incarcerated, experience has shown that such incarceration is extremely rare and may practically be excluded from consideration. During the past nine years the author has examined 1,000 pregnant women who, in the first months of pregnancy, showed a retroflexed uterus, yet only in two instances was the uterus incarcerated. In all the others the uterus righted itself so as to assume its normal position as the pregnancy advanced. The author believes that most practitioners bestow entirely too great a significance upon a retroflexed uterus, and that the symptoms caused thereby are in the vast majority of cases due to accidental complications, such as endometritis, hysteria, etc. Furthermore, that the best results are to be obtained by treating these conditions rather than by replacing the retroflexed organ.

French and Italian Journals.

Purulent Infiltration of the Cervix.—Chéron reports the case of a woman who was suffering from a severe infection. The uterus was disinfected several times energetically, but the patient quickly succumbed. At autopsy it was discovered that the uterus appeared perfectly healthy to the level of the cervix, but at this part it was profoundly altered. The cervix was very much enlarged and œdematous, and on section there was shown to be a true purulent infiltration, which was limited by the internal os. These cases of infection localized in the cervix are exceptional. It shows that if supravaginal hysterectomy were practised in these cases the healthy parts would be removed while the diseased parts would be left behind —*Le Bulletin Médical*, July 12, 1902.

The Influence of Thyroid Medication on the Pruritus of Jaundice.—Gilbert and Herscher declare that the ingestion of thyroid extract will cause the disappearance of, or at least will greatly ameliorate, the pruritus of jaundice. Under the influence of this medication, the reaction of Hay is modified, and as it is admitted that the pruritus is due to the action of the bile salts on the terminations of the nerves, these authorities have come to the conclusion that thyroid extract exercises over the bile salts a destructive or modifying influence. Solutions of the bile salts mixed with thyroid extract and injected into the vein of a rabbit's ear, are much less toxic in their effects than are the pure solutions of the bile salts. Thus it is shown that thyroid extract is a prophylactic against poisoning by biliary salts.—*Le Bulletin Médical*, July 30, 1902.

The Rôle of the Lymphatic Ganglia in Protecting the Organism from Tuberculosis.—Luigi Manfredi and B. Frisco conclude from their experimentation that it is possible, by means of endolymphatic injections of tubercular bacilli, to produce a tuberculosis which remains localized in the lymphatic system. The glandular system exercises a certain protective influence not only toward itself but toward the organism: (1) By a mechanism which arrests or retards further progress of the bacilli, and which is due partly to the natural structure of the ganglia and partly to inflammatory processes initiated in the ganglia by the presence of the bacilli; (2) By an influence which attenuates the virulence of the bacilli, and which is slowly germicidal; (3) By a marked tendency to sclerosis of the infected gland. The defensive powers of the lymphatic ganglia can be experimentally increased, or, in other words, a certain degree of immunity against tuberculosis produced by repeated endolymphatic inoculations with small doses of tuberculous virus. *Il Policlinico*, July, 1902.

Little's Disease.—Mariano Salaghi reports six cases of this affection. Two of them presented the rare complication of atrophy ,and degeneration of the thenar eminence and of the interosseus muscles of the hand. This demonstrates that although the greater number of symptoms in Little's disease point to a cerebral lesion there may be at times cœxist lesions of the spinal motor cells. The affection should be considered a paresis of cerebral origin, rather than a paralysis. In the cases reported the disease did not occur until between the fifth and tenth year, so that for the theory of arrested development there should, perhaps, be substituted the theory that there is an hereditary lesion or a lessened resistance of some of the cortical motor neurones, resulting in their degeneration and destruction of a certain number of nerve units. From the course of the disease in these cases it would seem fair to infer that when the disease develops late it is of graver import than when it begins with birth or shortly after.—*Rivista Critica di Clinica Medica*, July 19, 1902.

Importance of Toxic Phenomena in Appendicitis.—Dieulafoy gives the results of his wide observations in cases of appendicitis. He states that every case of acute febrile appendicitis, even with a rapid course, has been cured when operated on within the first two days; the cases operated on the third day have generally been cured, but not always; from the fourth day, some cases are cured, while others succumb. It is often difficult to tell just when an attack has begun. Appendicitis often exists twelve or twenty-four hours before any great pain or severe symptoms occur. He says, for example, a patient is attacked by appendicitis with slight symptoms; there is no severe vomiting. But the general condition becomes worse, the skin becomes leaden in tint, and the urine is less abundant, and contains albumin and casts. At operation there is slight peritonitis, but a rectocæcal abscess and some gangrene of the posterior wall of the appendix. In spite of the operation, the patient sinks, and finally, after severe attacks of hæmatemesis, he succumbs. At autopsy there is only a little pus in the peritoneum, and the viscera appear normal to the naked eye. But the kidneys, on careful examination, show an acute degenerative nephritis, due to the action of toxins. It is clear case of toxic appendicitis. In dealing with this affection it is very necessary to know its stage.—*La Médecine Moderne*, July 9, 1902.

Tubal Pregnancy: Intraperitoneal Hemorrhage.—René Tesson states that tubal pregnancy is of frequent occurrence. It presents itself in various forms, and it is accompanied by diverse accidents, chief among which are hemorrhages. The writer reports several cases. One of these patients was a domestic, twenty-eight years old. She had always menstruated normally. She had one child three years old. She did not remember the exact date of the last menstruation, but a few weeks later she was taken with acute abdominal pain and vomiting. She was not confined to bed, but continued to suffer for more than a week. A few days later she came to the hospital. Examination showed that the uterus was displaced by a soft mass which was diagnosed as a retrouterine hæmatocele. The patient was ordered to be kept in bed under observation. Suddenly, after the examination, the patient gave a cry, and it was evident that there had been a sudden hemorrhage and there was not a minute to lose. Laparotomy was at once performed. The abdomen was filled with blood, which came from the right tube. This was excised and the abdomen and pelvis were cleaned out. A drain was inserted behind the uterus, and the wound was closed. Intravenous injection of serum was made during the operation. The fetal cyst had been ruptured on its anterior surface. Convalescence was rapid and uneventful. This case shows how precarious the condition of these patients is. When the diagnosis is made, it is best to do an early operation, in order to prevent such accidents.—*Gazette des Hôpitaux*, July 8, 1902.

Annals of Surgery, August, 1902.

A Case of Splenectomy for Leukæmic Enlargement.—Theodore A. McGraw operated on a child of eight years, with a fatal result. The disease was of at least two years' standing. The author holds that the danger of operation is in exact ratio to the previous duration of the disease. To be able to operate early, we must get the cases early, and to this end the general practitioner should coöperate with the surgeon, and make examinations of the blood as a routine procedure in all cases of wasting disease.

Morrison's Operation for Ascites Due to Laennec's Cirrhosis.—F. Tilden Brown reports a case, and reviews others. Fifty per cent. were greatly improved or cured. He says, in conclusion, that the more rapid the accumulations of ascitic fluid, have been the greater the reason to provide for long-continued drainage, which is to follow the operation, and to expect that very gradual improvement in all symptoms is the most and best which can be hoped for. The value of Morrison's adhesive strapping to keep in approximation the denuded peritoneal surfaces, and at the same time to compel the serous effusion to find its only available space in the pelvis, is evident. The importance of the long continuance of this device was accentuated on two occasions, when a hospital interne attempted at the end of four weeks, and again later, to dispense with the adhesive strapping, each time an accession of ascitic fluid to the upper part of the peritoneal cavity was apparent.

Congenital Dislocation of Hips.—Edward H. Ochsner describes the "bloodless functional weight method" of Lorenz, which consists in reduction, reposition, formation of acetabulum, and restitution of function, these different acts not always following each other in regular order, but some of them occurring more or less simultaneously. If untreated, the disease has a bad prognosis, the unsightly deformity persisting throughout life. The power of endurance becomes greatly reduced, and pain may be slight or so severe as to incapacitate the patient for all work requiring walking or standing. If the patient is submitted to the bloodless operation before the age of six years in double and ten in single dislocations the prognosis is much better. In 212 carefully-observed cases Lorenz reports 108 anatomically and functionally perfect results, 102 anatomically imperfect, but functionally good, results. The author reports six cases of his own.

Angiotripsy as a Substitute for the Ligature in Routine Work of General Surgery.—Oscar J. Meyer describes his experimentation on animals with his simplified angiotribe. No secondary hemorrhages were encountered in any of them, though no bandage nor immobilization were employed, and the animal was allowed to roam at large after the third day. The specimens obtained show that the tissues thus treated are not devitalized and do not become necrosed, but are only powerfully compressed, the life of the cells not being destroyed. In many cases angiotripsy will render drainage obsolete, or considerably curtail the time necessary for its employment, as well as greatly lessening the chances of infection, by restricting secretion. Another advantage is the reduction of suffering to a minimum, as angiotripsy crushes the nerve. This is very noticeable in operations for hemorrhoids. In extirpations of extensive cervical tubercular or carcinomatous glands, and in thyroidectomy angiotripsy has rendered the author excellent service. In a friable organ, as the liver or the kidney, and in a sinus, like in the dura mater, it is of no avail.

Complications Following Gastroenterostomy.—William J. Mayo reports 107 cases of gastroenterostomy with ten deaths, due to exhaustion, exhaustion with pernicious vomiting, progressive pneumonia, and detachment of the anastomosed intestine from the stomach-wall. The deaths from exhaustion were due to the extreme starvation which existed at the time of operation. The latest theory in regard to the frequency of lung complications following operations on the stomach is that some of the venous blood returning from the stomach does not pass through the portal vein, and in this way infected emboli are carried directly into the circulation and pass at once to the lungs. The two cases in which the anastomosed intestine was detached occurred in one case from an amount of free fluid present, in the other after an epileptic seizure. The most important feature in the mechanics of the anastamosis is that the union shall be at the inferior border of the stomach, close to the greater curvature, and at the bottom of the stomach-pouch, giving a funnel shape. The anastomotic opening should have its inferior border at the bottom of the stomach, and as to whether the opening shall extend from this point upward anteriorly or posteriorly is of little moment.

The Edinburgh Medical Journal, August, 1902.

Some Functional Neuroses of the Throat.—P. M'Bride reports a case of *laryngeal*, or *pharyngeal whistling*,, due undoubtedly to neurasthenia. Second, third, and fourth cases are of *functional aphonia*, caused in one case by fright; in one by neurasthenia, and in one by a hysterical temperament. The voice returned as suddenly as it had gone in the first case, and in the others as a result of tonic treatment. *Inspiratory spasm* has been met with by the author several times, which bore the closest resemblance to bilateral abductor paralysis, but the fact that the patient suffering from inspiratory spasm sleeps quietly, while in abductor paralysis the respiration is noisy, affords a means of distinguishing between the two conditions. Holding the nose and mouth shut for a few seconds, is, in the case of inspiratory spasm, followed by a full, quiet inspiration, which test gives a ready method of differentiating the two conditions. The author would, however, feel disinclined to risk it, unless the presumption was in favor of the functional ailment.

Insects and Cholera.—Andrew MacKaig describes an outbreak of cholera in India which seemed to appear almost simultaneously in different parts of the country, but in every case where large numbers of people were gathered together on famine relief works. The chief point of interest is how the disease attacked persons who had no relation whatever to contaminated water and were most careful in all hygienic measures. The number of flies swarming about every article of food was beyond description, and at Godhra, in the house where the author lived, every care was taken to prevent flies settling, and there were no cases of cholera. He holds that the number of cholera cases varied in direct proportion to the number of flies at any given time. Certainly, cholera and flies increased and decreased with each other. Native cholera sufferers are usually found lying on the floor, covered partially with a few rags, the ground being in a state too awful to be described. A cloud of flies is present, which rises with a loud hum on a motion being made near the patient, but at once settle again. It is hard to see how these flies could escape being cholera carriers.

The Causal Relation of Cocci to Rheumatism.—W. Blair Bell is convinced that all *acute* rheumatic affections are of microbic origin, and, further, that they are of coccal causation. Also that the source of infection is sometimes obvious and sometimes obscure. Further, he thinks that those specially called "rheumatic," as opposed to pyemic suppurating lesions, are produced by a toxin circulating in the blood without an accompanying army of cocci; but that certain of the cocci, *e. g.* pneumo- and gonococci, do frequently invade the joint and produce symptoms which are no longer purely "rheumatic." From this multiplicity of determing factors he concludes that "rheumatism," in its acute form, is a *symptom* only of many toxæmias and not a clinical entity; chronic rheumatism being a *symptom* of some perverted chemical change, associated with cold food, nervous changes, etc. Finally, he believes that the so-called specific diplococcus is a modification of either the strepto- or staphylococcus—an attentuated variety—and that it is by these that the ordinary non-suppurating "rheumatic fever" is pronounced. He says, however, that his statements lack absolute proof and are merely of a suggestive nature.

Therapeutic Hints.

Cancer. Take galangal root, grate or pulverize to fine powder, add zinc chlorid, make plaster and apply all over the cancer surface; renew every day until the cancer begins to give way from the healthy tissue. I generally let the plaster stay on the cancer about four or five days, then remove and apply any good salve. In about ten or fifteen days you can remove the entire growth, and the place will heal very readily. With but few exceptions the knife is a failure. —W. S. Robinson.

How to Take Castor Oil.—The disgust for castor oil is due to the odor, not to the taste. If the patient grips the nostrils firmly before pouring out the dose, drinks same complacently, and then thoroughly cleanses the mouth, lips, larynx, etc., with water, removing the least vestige of the oil before removing the fingers, he will not get the least taste from the oil, which is bland and tasteless. It all depends upon keeping any air from entering the nose during the time while there is any oil present.

—F. S. Hough in *Iowa Medical Journal*.

Treatment of Locomotor Ataxia.—The most important consideration is, as a rule, rest in bed, which, if prolonged, often hinders the progress of the disease. In any case, undue fatigue or over-exertion should be avoided. The rest cure is eminently suited to this condition. The second great indication is good nursing and plenty of good rich food which contains very little fat. The third indication is frequent warm baths. The greatest benefit results from saline baths at a temperature of from 30° to 32°C. The bath should not, as a rule, last longer than fifteen minutes. Chills and sweating should be avoided and warm clothing should be worn. For individual symptoms, electricity, massage, narcotics, and analgesics are indicated. —*Indian Medical Record*.

Chionanthus Virginica. This drug is recommended for the relief of jaundice whenever there is no fixed obstruction. Whenever the jaundice comes on quickly, and is not of long standing, this drug will produce a speedy cure. Tenderness in the region of the liver is one of the indications for this remedy, and cases of long standing will most frequently be at least greatly benefited. It has a decided effect over the glandular structures, and is efficacious in recovering from bilious fevers and obstinant intermittants, and an herb tonic during convalescence. Dose is from gtts xiii to gtts xiv.

—Dr. Ellingwood in *Medical Summary*.

Book Reviews.

Clinical Lectures on Neurasthenia. By Dr. Thomas D. Savill. Second Edition. New York: Wm. Wood & Co.

This work has no pretension to being a systematic treatise on neurasthenia. It is simply a report of five lectures on this common disorder. Aside from some irrelevant matter concerning clinical teaching in Poor-Law Infirmaries (Lecture I), the lectures are readable and instructive. Lecture II is devoted to the general presentation of neurasthenia, its causation, course, and prognosis. Lecture III and IV are given up to the diagnosis and pathology of the disorder, while the mental symptoms of neurasthenia are considered in the last lecture. The author has been happy in his choice of illustrative cases, and this, coupled with considerable literary skill, makes the volume interesting and readable. The only criticism that might be offered is that the subject has scarcely been brought up to date. The book, of about 150 pages, is attractively printed and put together.

A Text-book of Insanity. By Charles Mercier. Lecturer on Insanity at the Westminster Hospital Medical School. New York: The Macmillan Company, 1902.

This little book of 220 pages has been prepared because year after year the author has had to recommend books on insanity to his students which he knew to be excellent in themselves, but which are too bulky and voluminous. This recalls the explanation that an American psychiatrist gave for writing his recent book, "The Absence from English Medical Literature of a Comprehensive Work on Insanity." Some modern writers of psychiatric textbooks would seem to have an inclination toward megalomania, which is easiest squelched when dealt with in its incipiency. There are not only a number of comprehensive works on insanity in the English tongue, but most excellent brief textbooks. Mr. Mercier devotes Part I of his book to a discussion of conduct, mind, certifiability, and fitness to be at large, and the causes of insanity; Part II to the forms and varieties of insanity, and Part III to the legal relations of insanity. Taking it all in all Part I may be said to be a satisfactory brief presentation of the institutes of insanity, and the same may be said of the chapter on the causes of insanity. The sections devoted to the varieties of insanity do not merit similar approval. The sections on dementia and acute insanity, are, in the opinion of the reviewer, unworthy of favorable comment. For instance, we do not believe that the writer voices the opinion of many psychiatrists when he says "The only form of dementia which has a true clinical distinctness and constitutes a separate clinical entity is that which is known as stupor," unless he applies the designation stupor to the clinical picture which most modern psychiatrists give the designation dementia precox.

Nothing is said of the treatment of insanity, and, save the stereotyped description of the changes in the brain in general paresis, nothing is said of the pathogenesis and morbid anatomy of any of the forms of insanity. These may not be considered by the author serious deficiencies in a textbook, but they are so considered by the reviewer. If the general practitioner has a standard book on mental diseases, like Macpherson's or Kraft-Ebing's, and desires to get another psychiatrist's point of view, we recommend Mercier's little book.

Clinical Psychiatry: A Text-book for Students and Physicians. By A. Ross Defendorf, M.D. New York: The Macmillan Company, 1902.

The above title conveys no idea that this volume is in reality an abbreviation of Kraepelin's "Lehrbuch der Psychiatrie," although this fact is set forth on the title page. The book is being advertised, however, as a textbook of Clinical Psychiatry by a gentleman who has not written a word of it and who is not responsible for a statement contained therein, but who, nevertheless refers to himself in the preface as the author. "It was the author's first intention to publish a complete translation of Kraepelin's "Lehrbuch," but it was feared that it would be too large to subserve the function of a textbook, and would have rendered impossible the daptation of the Kraepelin phsychiatry to our peculiar American needs." Just what is meant by the latter half of this sentence the reviewer does not know. All that seems clear to him is that Dr. Defendorf started to translate Kraepelin's textbook, and finding that it would make a large volume, Kraepelin's textbook *being* a large volume, he went through it with a pair of scissors and called himself the author of a book on clinical psychiatry and thanked two fellow psychiatrists for "their continued inspiration." This is a new way of book-making, and we can imagine that it requires inspiration to do it. We trust sincerely that no injustice is being done Dr. Defendorf, one of the earnest and advanced workers in the field of psychiatry in this country. It may be that Prof. Kraepelin has authorized him to translate and epitomize his book, or it may be that the publishers are taking it upon themselves to advertise this book as Defendorf's Psychiatry. If so, fairness and justness to the world-renowned author demand that these facts be set forth.

The contents of the volume are a brief presentation of the facts of general symptomatology and a consideration of the different forms of mental disease. Under the latter are discussed the infection, exhaustion, intoxication, and thyroigenous psychoses, dementia precox, dementia paralytica, organic dementia, involution psychoses, maniac-depressive insanity paranoia, the general neuroses, constitutional psychopathic states and defective mental development.

While we gladly welcome any publication that makes Kraepelin's interpretations and descriptions more widely known, we deprecate the way in which it is done in this instance.

Die Aetiologie des akuten Gelenkrheumatismus nebst kritischen Bemerkungen zu seiner Therapie. Von Dr. A. Menzer, Stabarzt und Assistenten der iii. med. Universitätsklinik der Kgl. Charité. Mit einem Vorwort von Prof. Dr. Senator, Geh. Med.-Rath. Berlin: 1902. August Hirschwald.

This interesting volume, although concisely written, views the subject treated from various standpoints. The first chapter gives a review of the older bacteriological experiments which were conducted with a view to clearing up the etiology of acute articular rheumatism, including results of examination of the blood, of the vegetations on the heart valves, the pleural exudate, and the urine. Then follows an account of the recent experiments on animals. The writer discusses the relation between the streptococcus found in the tonsils and acute articular rheumatism. A chapter on treatment is given. There is an extensive bibliography, and a number of beautifully colored plates. The volume is a valuable contribution to the study of acute articular rheumatism.

Le Mal de Mer. Comment on s'en préserve, comment on en guérit, comment on le soigne. Guide Hygiénique Complet du Vogageur à bord des Navires. Publié par le Comité de la Ligue contre le Mal de Mer, sous la Direction du Docteur Madeuf. Paris, 1902.

This little book is one of the first fruits of the recently established League against Seasickness. It is an exceedingly interesting book to read, and its optimism would be most comforting could one only forget the proved worthlessness of so many vaunted sure cures or preventives of seasickness. The author of this book, however, puts forward the claims of no specific—says, indeed, that there is no specific—yet asserts, with all the positiveness of conviction founded upon ample experience, that seasickness is a true disease, and that it is preventable and curable. The directions for those who would voyage with pleasure and freedom from illness are most explicit, beginning with a preparatory course of treatment before going on board, and continuing through the preliminary stages of apprehension and slight discomfort to those of nausea, dizziness, emesis, despair, and indifference to fate. It is fair to presume, however, that those who follow the early instructions will have no need of the therapeutic counsels for the declared disease.

Practical Dietetics, with Special Reference to Diet in Disease. By W. Gilman Thompson, M.D., Professor of Medicine in the Cornell University Medical College in New York City; Visiting Physician to the Presbyterian and Bellevue Hospitals. Second edition, enlarged and thoroughly revised. New York: D. Appleton and Company, 1902.

Since the first edition of this book, published in 1895, there has been an increasing interest in the medical profession in the subject of diet in health and disease, and we doubt not this increase is due in part to Dr. Thompson's excellent work. One may have a general idea regarding the nutrient value of some of the more common foods, and a more particular and personal knowledge of their differences in digestibility, but this is a very slender foundation upon which to base a dietetic prescription. Hence the need of such a work as this, in which the subject of dietetics is handled in much the same way as that of drugs is in a treatise on materia medica. In the present edition there is not a great deal that is different from the old, except for some thirty pages of new matter, largely based upon the publications of the Department of Agriculture. The most important changes are in Part VIII, dealing with Diet in Disease, and these sections are eminently satisfactory and practical, furnishing a trustworthy guide to the physician in this difficult field of practice.

The Essentials of Histology, Descriptive and Practical. For the Use of Students. By E. A. Schäfer, LL.D., F.R.S., Professor of Physiology in the University of Edinburgh; Formerly Jodrell Professor of Physiology in University College, London. Sixth Edition. Revised and Enlarged, with 463 Illustrations. 416 pages. Philadelphia and New York: Lea Brothers & Co., 1902.

This edition has been markedly enriched by the addition of many original and selected illustrations, to such an extent, in fact, that it could well serve as instructive reading without the use of microscopical preparations to one familiar with the same. The work is divided into lessons, at the beginning of which full directions for the technique of the preparation of special specimens are given. The author has disregarded the unimportant details and has confined his description to the essentials, thus making the book particularly well adapted to beginners. In this issue the chief changes to be noted are the enlargement of the chapters on the central nervous system together, with the new and most admirable illustrations.

The Roller Bandage. By William Barton Hopkins M.D., Surgeon to Pennsylvania Hospital, etc. With Illustrations. Fifth Edition. Revised. Philadelphia: J. B. Lippincott Company, 1902.

The student is often required to show theoretical and practical proficiency in bandaging, and a convenient textbook dealing with the subject is often of value. This little volume fills such a place exceedingly well, and its popularity is attested by the fact that this is the fifth edition. The best part of the book is the illustrations, which are graphic and excellently executed.

A Manual of Instruction in the Principles of Prompt Aid to the Injured, Including a Chapter on Hygiene, and the Drill Regulations for the Hospital Corps, U. S. A. Designed for Military and Civil Use. By Alvah H. Doty, M.D., Health Officer of the Port of New York, etc. Fourth Edition, Revised and Enlarged. New York: D. Appleton & Co., 1902.

This edition is an enlargement of those which have preceded it, and a number of changes have been made with a view to meeting the latest requirements. The chapter upon disinfection has been especially improved, and the introduction of the army-drill regulations adds considerably to the value of the book from the military point of view. The volume is especially useful to nurses, orderlies, and hospital stewards, who will find it a serviceable work of reference.

The John Hopkins Hospital Reports. Volume X., Nos. 3, 4, and 5. Baltimore: The Johns Hopkins Press, 1902.
The present volume contains the following four monographs: "On the Pathological Changes in Hodgkin's Disease, with Especial Reference to Its Relation to Tuberculosis," by Dorothy M. Reed; "Diabetes Insipidus, with a Report of Five Cases," by Thomas B. Futcher; "Observations on the Origin and Occurrence of Cells with Eosinophile Granulations in Normal and Pathological Tissues," by W. T. Howard, Jr.; and R. G. Perkins; and "Placental Transmission, with Report of a Case During Typhoid Fever," by Frank W. Lynch. In the article on Hodgkin's Disease there are some very interesting clinical histories given, and it is embellished by fine plates. The writer of Diabetes Insipidus gives a summary of his paper, together with a valuable biography. A short summary, with a colored plate illustrating various cells, concludes Eosinophile Granulations. There is an elaborate biography appended to Placental Transmission. The volume taken as a whole is very pleasing and represents the work for which the Johns Hopkins Hospital is noted.

Neurasthenie und Hysterie bei Kindern. Von Dr. Alfred Saenger, Nervenarzt in Hamburg. Mit zwei Abbildungen im Text. Berlin: S. Karger, 1902.

The author considers his subject under four heads: Neurasthenia, hysteria, associated neurasthenia and hysteria, and hereditary neuropathy.

The Physician and His Patient, or The Business and Social Relation Which Should Exist between Them. By A. E. Lawrence, Cincinnati. Press of Jennings & Pye, 1902.

In this little book of forty-eight pages the writer vividly depicts the annoyances to which the physician is almost constantly subjected. The ideal relations which should exist between him and his patrons are described. A few words are given to the consideration of the quack. The average life of the physician, as computed by mortality tables, is given as fifty-six years.

Alkoholismus im Kindesalter. Von Prof. Dr. Max Kassowitz, Direktor des ersten öffentlichen Kinder-Kranken-Institutes in Wien. Berlin: S. Karger, 1902.

The writer gives a number of very interesting cases of alcoholism in children, and then considers alcohol from various points of view as a therapeutic agent.

Atlas and Epitome of Abdominal Hernias. By Dr. George Sultan, First Assistant in the Surgical Clinic in Gottingen, Prussia. Authorized Translation from the German, Edited by William B. Coley, M.D., Clinical Lecturer on Surgery, Columbia University (College of Physicians and Surgeons); Surgeon to the General Memorial Hospital; Assistant Surgeon to the Hospital for Rupture and Crippled, New York City. Philadelphia and London. W. B. Saunders & Company, 1902.

This little volume will, undoubtedly, prove valuable both to the general practitioner and to the surgeon. It is profusely illustrated, and each plate is clearly described. Hernia in general is first treated. Then follows the subject of special hernias, including inguinal, femoral, umbilical, obturator, sciatic, perineal, inguinoperineal, diaphragmatic, ventral, lumbar, and the several varieties of internal hernias. The special features of this book are the illustrations and the attention which is paid to the surgical intervention in hernia. The Surgical Clinic at Göttingen and the Institutes of Anatomy and Pathology were sources from which the author has derived abundant material. There is a convenient index appended.

Tuberculous Otitis Media.—G. K. Grimmer offers the following conclusions: (1) Advanced tuberculous changes may be present in the mucous membrane of the tympanum and of the tympanic membrane itself without producing visible evidence through the external auditory meatus; (2) The membrana propria of the drumhead offers marked resistance to tuberculous infiltration and is only destroyed by a process of erosion. This resistance also accounts for the frequency of multiple perforations in tuberculous cases; (3) Latent tuberculous nasopharyngeal adenoids and all other latent foci must be excluded before deciding that any case of middle-ear tuberculosis was a primary infection; (4) A high percentage, probably 65–70 per cent. of cases of suppurative otitis media with neighboring bone lesion, in children under five years, are tuberculous; in older persons, not more than 16 per cent. of similar cases are tuberculous; (5) Intraperitoneal inoculation of guinea-pigs is a good and reliable method of proving the presence or absence of tuberculosis in granulations from the middle ear. Reliable proofs may also be obtained by examining, microscopically, such granulations or even an enlarged mastoid gland or nasopharyngeal adenoids when present; (6) In cases of suppurative otitis media, the absence of ear pain, early and extensive destruction of bone, early facial paralysis, multiple perforations, pale, flabby granulations with caseous points in the meatus, about a mastoid sinus, and in the mastoid antrum, and an enlarged mastoid gland point strongly to the disease being tuberculous; (7) The detection of bare bone with a probe through the meatus, the character of the discharge, facial paralysis, and extensive destruction of bone appearing as a late symptom, are of doubtful value in arriving at a diagnosis, while the presence of cholesteatomatous masses is positively opposed to tubercles being present.—*Archives of Otology.*

The Criminal Use of Chloroform.—J. Howe Adams cites some cases in Dr. Quimby's experience, from which two important inferences may be drawn. First, that minor surgical operations, such as opening abscesses, removing ingrowing toe-nails, etc., may be done with perfect safety and much more pleasantly than in the ordinary way. Secondly, a person somewhat skilled in the use of chloroform may enter the sleeping apartment of a person or persons and administer the drug with evil intentions. Hence the use of chloroform in the hands of the criminal may become an effective instrument in the accomplishment of his nefarious designs.—*The Medical Age.*

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventieth Annual Meeting, Held at Manchester July 29, 30, 31, *and August* 1, 1902.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 280.)

SECTION OF TROPICAL MEDICINE.

Wednesday, July 30.—*First Day.*

President's Address.—Sir WILLIAM R. KYNSEY, C.M.G., in his opening remarks said that in the history of the past year there was no great discovery to be recorded; it might be looked back upon as one of steady progress in elucidating some of the many problems of tropical medicine, the greatest and most beneficent being in the scientific prevention of disease. In the case of yellow fever the mosquito had been tried and found guilty of being the sole agent in the spread of that disease. In Havana yellow fever was endemic for a century and a half; during the past year it had been freed from the scourge by the destruction of the mosquitos in the neighborhood of each focus of disease as discovered, and by careful disinfection of every house that had lodged a yellow-fever patient, in order to destroy the mosquitos that had bitten a sick person. This great sanitary triumph must ever redound to the honor of American medicine.

Prophylaxis of Malaria.—No excuse, the speaker continued, was necessary for dwelling a moment on this important subject. He had high authority for the statement that, taking one year with another, malaria destroys twice as many people in India as cholera, small-pox, and all other epidemic diseases put together. It was a matter of history that the same cause almost annihilated the soldiers of the Walcheren expedition, and the army under Wellington in Spain was so assailed by malaria that, according to Ferguson, the enemy and all Europe believed the British forces were exterminated. Malaria stopped the great Panama scheme of de Lesseps. The speaker had known districts in Ceylon almost depopulated. A most disastrous outbreak occurred some years ago at Galle—a town previously malaria free—attended with great loss of life, in consequence of the construction of a railway, the embankments of which were made by excavating pits at the sides, that soon were filled with rain water. In those days the origin of the fever was, of course, attributed to disturbance of soil. We now know the pits provided breeding places for the Anopheles, and the Singhalese and Tamil laborers from malaria districts supplied the organisms. Although ignorant at the time of the true conditions which caused the outbreak, Sir William advised the filling up of the pits on the disturbance of soil theory with satisfactory results.

It will be interesting to recall two experiments—one made by the Colonial Office on Dr. Manson's advice, and the other by the Japanese Government, which clearly showed it to be both possible and practicable to prevent malarial infection. In the experiment conducted by Drs. Sambon and Low in the Roman Campagna and in London in order to prove the truth or error of the mosquito malarial theory, and also how far protection against malaria might be consistent with the ordinary avocations of life, two experiments were necessary, one that healthy persons in London should be bitten by infected mosquitos from a malarious region, and the second that men should live in an undoubtedly malarious place during the fever season, being protected only from the bites of mosquitos. Those bitten in London contracted ague. Drs. Sambon and Low and two others lived in a mosquito-proof hut in a most intensely malarious place in Italy, where all the inhabitants suffered from malaria. The four inhabitants of the hut remained perfectly healthy all the time. The experiments by the Japanese Government were carried out on the Island of Formosa, and they furnished a most conclusive demonstration of the relations between mosquitos and malaria. A battalion of soldiers, who were completely protected from mosquitos for 161 days during the malaria season, escaped the disease entirely, whereas there were 259 cases of malaria in another battalion in the same place and during the same length of time not protected from mosquitos.

By a study of the life-history and surroundings of the Anopheles, and by varied and long-continued experiment, Ross has determined the best means of preventing malarial infection. He advised the extermination of the Anopheles, and although this was difficult it was not so difficult as it appeared at first sight. These mosquitos breed in small pools of a certain kind easily recognized and easily dealt with, always close to human habitations, as the females must pass frequently between the pools where they lay their eggs and the houses where they obtain their food. If the Anopheles are found in a house the breeding puddles are close by. The great practical points derived from Ross's work are two: (1) That the life of the Anopheles is in direct and intimate relation with the annual epidemics of malarial fever; (2) That it is only necessary to drain the Anopheles puddles and not the whole of a malarious district.

The discovery of the malarial parasite, and the investigations into the life-history of the mosquito which conveys it to man, have placed us, the speaker said, in the position to suggest measures which, if carried out, would have the effect, in an unhealthy district, of largely reducing the amount of malarial fever and eventually of exterminating it: (1) Malarial fevers should be included and notified among infectious diseases, so that precautions could be taken to prevent their spread; (2) Persons, especially children, suffering from malaria should be isolated and treated with quinine, to prevent as far as possible the infection of mosquitos; (3) Persons infected with malaria should be prevented from coming to a healthy place to infect mosquitos; (4) The puddles in which the Anopheles breed should be drained and filled up or treated with kerosene to destroy the larvæ; (5) Doors and windows of houses in malarious districts should be screened with wire gauze, and beds should be provided with netting, to prevent mosquitos from entering and biting the occupants.

Discussion on Beriberi.—Dr. PATRICK MANSON, C.M.G., F.R.S., opened this discussion by stating that it was of importance that from the outset we should be in agreement as to what the word beriberi indicated. The term had been applied to a variety of morbid conditions, and it was not quite certain that it was always correctly employed. Several specifically distinct forms of neuritis were grouped together under the term beriberi. Clinically, beriberi was a multiple peripheral neuritis. There were, from the etiological standpoint, many kinds of peripheral neuritis, but though etiologically distinct, all kinds had necessarily many clinical symptoms in common. Arsenic had been accredited with causing a polyneuritis akin to beriberi, but it was quite certain that what was generally regarded as beriberi had nothing to do with arsenic. One often heard of malarial neuritis, and sometimes even of small epidemics of what was described as malarial neuritis, but Dr. Manson was convinced that the vast majority of cases and epidemics were really of beriberi. He quoted two cases in which malaria and beriberi appeared to run concurrently, but he had seen tuberculosis combined with malaria, and there was no more reason to associate malaria with tuberculosis than with beriberi. In coming to a conclusion concerning an exact diagnosis in beriberi, the marked proneness to cardiac implication seemed to be a distinctive feature, and Dr. Manson would tabulate the signs and symptoms of beriberi as follows: (1) The ignorance of the cause of the disease; (2) Its occurrence endemically and epidemically; (3) The proneness to cardiac disability and dropsy; (4) Non-implication of the cranial nerves, with the exception of the pneumogastric; (5) Non-implication of the intellectual and emotional centers; (6) Rarity or complete absence of trophic skin lesions; (7) High rate of morality under certain conditions.

The immediate cause of beriberi, whether germ, toxin, inadequate and insufficient food, or traumatism, was unknown. Dr. Manson personally believed that what was called beriberi was produced by a toxin, the product of a germ operating in some culture medium located outside the human body. Further, the same toxin entered the body neither in food nor in water. He was thereby forced to conclude that the toxin was introduced through the skin or that it was inhaled. A beriberi patient was best treated by removal from the place in which he sickened—a fact which suggested, if it did not prove, that the cause of beriberi could not be a germ living and multiplying within the body of the patient, for if such were the case the patient when he left the endemic spot would still carry the germ with him. No satisfying proof of the existence of a specific germ in the blood of beriberi patients had been made. That the toxin of beriberi was produced by a living germ was shown by the fact that the disease could be introduced into virgin country and there spread. That is to say, the hypothetical cause was capable of being transported and of multiplying. Spontaneous multiplication was a property peculiar to living things; therefore the originating agent of the toxin of beriberi must be a living thing—a germ.

Undoubted proof that food had nothing to do with beriberi had been supplied recently by the observations of Dr. Travers of Knala Lumpor, Malay Peninsula. The observation was as follows: In Knala Lumpor, in 1895, there were five large institutions, in four of which beriberi had never been known. In one of the five institutions—what is known as the new jail—within six or seven months of its opening, beriberi broke out, and the disease, had stuck to it ever since. The food supplied to all the five institutions, or at all events the rice, was of the same kind and quality. Moreover, on removing a certain proportion of the sick from the new to the old jail, beriberi disappeared from among them, while in the new jail the disease continued to prevail. Not only was the food the same for all the institutions, but it was actually cooked in the same vessels.

Dr. Manson inferred from this experience of Dr. Travers that beriberi had no direct, if any, connection with food, most certainly not with rice.

That beriberi was not conveyed by drinking water had been many times proved, and required no further confirmation. As, therefore, beriberi was not caused by a germ operating directly in the human body, it could not pass as an infection directly from man to man. It would seem, therefore, that beriberi was the result of a toxin conveyed to man either by the air or through the skin by contact or by means of some insect or other animal which inserted it under the skin, or by a combination of two or more of these ways.

The Cause of Beriberi.—Captain E. R. Rost, I.M.S., said that he had found in rice liquor as sold in native shops in India and Burmah, a diplobacillus. He found the same bacillus in pigeons that had been allowed to feed on infected and mouldy rice, and he experimentally produced with this microbe a disease in birds similar to beriberi. He summed up his conclusions regarding the etiology of beriberi as follows: (1) By feeding fowls on fermenting rice obtained from the rice-liquor shops, he had induced a disease similar to beriberi. (2) He induced the same symptoms (*a*) by feeding the fowls on mouldy rice obtained from the lower bags of damp godowns; (*b*) by intraperitoneal injection of rice-water liquor; (*c*) by subcutaneous or intraperitoneal injection of the venous blood of beriberi patients; (*d*) by reinjection from fowls suffering from the disease produced as above. From these experiments and from his observations on human beings, Captain Rost concluded that rice was the food whereby beriberi was originated.

Dr. L. Sambon said that he could not agree with Dr. Manson that Dr. Travers' experiment swept away the vast amount of evidence in favor of rice being a possible factor in the etiology of beriberi. In the uncertain state of our knowledge he would restrict the diet in beriberi countries to strictly fresh rice; in coolie gangs previous sufferers from beriberi should be separated from others, and patients suffering from beriberi should be segregated within the endemic area, so as to prevent the spread of the disease to non-infected districts.

Major Ronald Ross, C.B., F.R.C., reported that he had examined chemically the hair from thirty beriberi patients, and in ten cases arsenic was found. He drew attention to the fact that it was only in the cases examined early in the disease that arsenic was found. This might be a mere coincidence or it might point to a real connection between arsenic poisoning and beriberi.

Dr. C. W. Daniels of the School of Tropical Medicine said that tropical peripheral neuritis included other diseases than beriberi, especially a post-dysenteric peripheral neuritis. Confusion existed in regard to the symptoms of beriberi, owing to many ailments being included under this generic title.

Dr. James Cantlie, M.B., F.R.C.S., said that the fact that beriberi was an infectious disease and not a mere famine illness should not be lost sight of. In a general ward in Hong Kong, in which were beriberi patients, he had seen the patients with open ulcers acquire beriberi in the wards while the medical cases escaped the disease. All were being supplied with the same food. He did not favor the rice infection theory, but at the same time he could not understand how, if the disease was dependent upon the presence of a toxin and not a germ in the blood, beriberi could be carried by patients and spread in virgin countries. If a toxin existed in the blood of beriberi patients and the germ which produced it had been left behind in the locality whence the beriberi patients sailed, it was inexplicable that the disease should spread to the persons in the new locality.

Dr. W. F. Prout, principal medical officer, Sierra Leone, described the arrival of a ship at Sierra Leone from Panama with 500 negroes on board. Half the negroes were suffering from beriberi, but, although they were brought on shore, the disease did not spread. He was therefore inclined to support Dr. Manson's theory that the disease was caused rather by a toxin than by a germ in the human body.

Dr. P. A. Nightingale (late of Bangkok) stated that beriberi was not endemic in Bangkok, Siam, but, although the people there fed on fresh rice some eighteen months ago, an outbreak of beriberi occurred there.

Sir William Kynsey, the President, said that, after twenty-five years' experience in Ceylon, he could safely say that there was no beriberi in that island. At one time, however, it was supposed to be so prevalent in Ceylon that it was called the Ceylon disease. He would like to know, in connection with the subject of arsenic and beriberi, whether the popular tale that the Styrian peasants ate arsenic in large quantities was true or a myth.

Thursday, July 31.—Second Day.

The Climate and Diseases of Bangkok, Siam.—Dr. P. A. Nightingale read this paper. The chief diseases met with in Bangkok, he said, were malarial fever of the estivo-autumnal type, dysentery of all varieties, but the ulcerative or gangrenous type were chiefly confined to Europeans; sprue was fairly common amongst Europeans; early morning or hill diarrhœa, so-called, was not uncommon; typhoid fever had been increasing in frequency lately; cholera was an annual visitant; leprosy was rife. The diseases more rarely met with were beriberi, malignant diseases (cancer, sarcoma), elephantiasis (filarial), dengue fever, latah (amok), and climatic buboes. Plague had not occurred in Bangkok.

Enteric Fever in Sierra Leone.—Major F. Smith, R.A.

M.S., read a paper on this subject. Although enteric fever was a rare disease in Sierra Leone, it would seem to be showing a tendency to increase in frequency. Many doubted the presence of typhoid fever in this district, but of thirteen cases recorded by Major Smith two gave a positive reaction by the agglutination test. So far as this test could prove the presence of typhoid, it was to be concluded that the disease did exist in Sierra Leone, and, considering the unsanitary environment, it was little short of marvellous that the disease had not spread.

Dysentery.—Andrew Duncan, I.M.S. (retired), opened the discussion on this topic. Under the term "dysentery" a number of ailments were grouped together, which, as investigation advanced, were coming to be differentiated. Of late years we had been made acquainted with the microorganism of Ogata and Shiga in Japan; of a similar organism discovered by Flexner in the Philippines; yet a third organism in Egypt; Celli and Fiocca in Italy held the bacillus coli dysenteriæ to be the exciting cause, basing their opinion on the fact that a toxin separated from the growth of the organism acted upon the intestines of animals; various pyogenic cocci and certain streptococci had been held responsible for the disease; the bacillus pyolaxeus in America and the paramœcium coli in Cochin, China, had each been accredited with being the originators of dysentery.

Dr. Duncan held the opinion that the amœba has nothing to do with dysentery in India, and he did not think that the evidence brought forward in support of the amœba coli as a cause of dysentery was convincing. The presence of this organism in dysenteric stools had frequently been denied, and there seemed, in cases in which it was present, to be no direct relation between the numbers of amœba found and the severity of the illness. It was also known that the amœba was found in the stools of persons suffering from diseases other than dysentery, and even in the normal intestine. In regard to the mortality from dysentery, a great deal depended upon the period of the disease when the patient came under treatment. Early treatment was imperative, and the extreme fatality one heard of was chiefly owing to the fact that dysenteric patients put off placing themselves under medical treatment until it was too late.

The treatment of dysentery varied with the type of the disease and, perhaps, with the country in which it occurred. In India there seemed no reason to discard ipecacuanha in acute cases. The treatment by salines had met with considerable success in India. In South Africa, during the war, ipecacuanha was given up and salines adopted. Treatment by the monsonia ovata had met with but indifferent success. Sulphur and Dover's powder found many advocates. In chronic dysentery Dr. Duncan gave binnatti twenty grains with one-quarter grain of Dover's powder (a seemingly ridiculously small dose); a dose of two drachms of castor oil every other night; a suppository of two and one-half grains of extract of opium every night; A dose of twenty minims of oil of turpentine, repeated when necessary, had many times proved beneficial. The question of opening the intestine in chronic cases was also worthy of consideration

Major W. J. Buchanan, I.M.S., Deputy Inspector of Prisons, Bengal, contributed a paper entitled "The Prevention and Treatment of Dysentery in Institutions in the Tropics." He held that one could now differentiate two great types of dysentery, namely, the (1) amœbic, and (2) the bacillary. The amœbic form, although generally known as the "tropical" variety of the disease, had no right to be so named, as it occurred in countries beyond the tropics. In India the bacillary form of the disease was much more common; practically the amœbic form was only recognized by the occurrence of liver abscess, the finding of the amœbæ, or the absence of reaction with Shiga's bacillus. Liver abscess was a very rare sequelæ of bacillary dysentery, except of the terminal gengrenous form; certainly it was practically unknown in the course of what was known in India as "gaol dysentery." Of 1130 cases of dysentery, on which Major Buchanan based his statements, not a single case of liver abscess was met with in the living or the dead. The dysentery of Indian prisons was probably almost entirely bacillary, and the tests made have shown it was due to Shiga's bacillus. We have no knowledge of how these organisms are carried into the body; polluted water might play a part, and the water theory would explain the epidemic prevalence of dysentery, but it would not so easily account for the endemic form. Good water, however, did not prevent dysentery. Dysentery was a seasonable disease. Moreover, outbreaks of dysentery coincided with badly-cleaned rice or wheat used as food. Dysentery would also seem to be a communicable disease, hence the necessity for isolation of patients, disinfection of clothing, etc., and the disinfection by lime and incinerations of all dysenteric stools. Major Buchanan advocated the saline treatment of the disease; of 1130 cases treated by this mode of treatment, the mortality had been under 1 per cent. Treatment by ipecacuanha had a place in therapeutics, but izal had failed.

Tropical or Amœbic Abscess of the Liver and Its Relationship to Amœbic Dysentery.—Dr. Leonard Rogers contributed a paper with this title. The statement made that natives of India rarely suffer from liver abscess was totally erroneous. The amœbiæ, although absent from the thick pus of a liver abscess, could always be found if the wall of the abscess cavity were scraped. The amœbiæ was well nigh constantly met with in liver abscess, for in thirty-five consecutive cases in which it was sought for it was found in the abscess wall. Cocci of suppuration were found in less than half the cases, while in the pus from just-opened abscesses they were obtained in only one-third. Even when found, pyogenic organisms were not necessarily virulent or capable of producing pus. The amœbiæ, therefore, seemed to be the only constantly found organisms in "tropical" or amœbic abscess of the liver. In regard to the relationship of dysentery to liver abscess a large proportion (95.83 per cent.) of cases pointed to dysentery being an invariable accompaniment of amœbic or tropical liver abscess. In 95 per cent. of Major Rogers' cases there was positive evidence of preceding dysentery. Leucocytosis was a marked accompaniment of liver abscess, and was most marked in those cases in which the disease was most difficult to diagnose, namely, the small deep-seated abscesses of the liver.

Dr. Patrick Manson said that he was inclined to regard treatment by ipecacuanha as an efficient remedy not only in the acute form of the disease but also in the chronic. The treatment must be kept up for at least nine days; daily doses commencing with, say, 30 gr of ipecacuanha and dropping gradually to 5 gr. daily being required. Rest in bed he considered a most important adjunct to treatment, and occasional doses of castor oil. Dr. Manson doubted the value of the serum test as applied to the bacilli of Shiga or Flexner. He also warned against the acceptance of the term "amœbic" as being applicable to a definite form of dysentery.

Dr. Edward Henderson, late of Shanghai, China, said that in his belief many patients with dysentery tended to get well without treatment, but if any particular drug had been given it was customary to attribute the improvement to that drug.

In all probability, rest in bed, suitable diet, and castor oil would cure most cases of catarrhal dysentery, but in cases of gangrenous dysentery no drug had been found efficacious.

Dr. W. G. Rockwood of Ceylon said that there seemed evidence to hand that dysentery was communicable; ipecacuanha had failed in his hands, but the saline treatment had given improved results. He had seen liver abscess in females, curiously enough in the left lobe

Dr. J. H. Musser of Philadelphia stated that he firmly believed in the relationship between the amœba coli and dysentery, and of this disease with hepatic abscess. It was a mistake to regard the disease as tropical, as cases had been found in the United States as far north as Michigan. Flexner had shown that the bacillus of Shiga was the cause of the dysentery met with in the Philippines, in the West Indies, and in several parts of America. The serum test seemed a reliable test in the recognition of the affection.

Dr. James Cantlie, late of Hong Kong, said that it was of some consequence to know how the saline treatment acted. If it was merely by "scavenging" the intestine, then it was surely the best plan in severe cases of dysentery to wash out the colon directly by cutting down on the ascending colon in the right lumbar region. He had met some seven or eight cases of liver abscess in persons who had only been in the tropics a few weeks, and who never had malaria, dysentery or any kind of intestinal flux. He could not agree with the apparently accepted doctrine that all liver abscesses were due to dysentery. In the cases he mentioned, the abscesses were all "suprahepatic" abscesses, and as he had shown before, these were different in their etiology and pathology from the "infra-hepatic abscesses," which he thought were almost invariably associated with dysentery.

Professor **Sandwith** of Cairo accepted the division of dysentery into amœbic and bacillary. He had believed for many years that dysentery is an infectious disease, and should be treated with the same precautions as typhoid fever. Weevil-eaten grain may be a cause of dysentery, as suggested by Major Buchanan, and it was noticeable that hellafra, a disease caused by diseased maize, often ended in dysentery both in Italy and Egypt. He had for some time renounced ipecacuanha as useless in dysentery. He had employed enemata extensively in treating dysentery ever since 1885, and he was fully convinced of its efficiency, and he injected at least one liter containing alternately boracic acid of sulphate of copper.

Inspector-General **Turnbull**, R.N., said that in Hong Kong he had seen gangrenous and catarrhal dysentery, and an aphthous form commencing with aphthæ of the mouth. In three cases of liver abscesses he treated by trocar and cannula successfully; there had been no dysentery before or after treatment.

Sanitary Work in West Africa.—Dr. M. Logan Taylor read this paper. The work carried on in several parts of West Africa during the past twelve months had been directed to ridding the towns and villages of the anopheles mosquito. The smallest pool would serve to harbor larvæ of anopheles; where the pools were small, the water was simply swept out; when the pools were larger, they were treated with some culicicide, either crude kerosene or crude creosote oil; other culicicides, such as formalin, corrosive sublimate, copper sulphate, carbolacene, etc., were tried, but they were less expedient and more expensive. A little oil was poured in a pool and the water well stirred up so that a film of oil spread over the whole surface. Natives very quickly learned how to do this. Crude kerosene thus applied would last a week if no more rain fell during that period. Crude creosote oil killed larvæ much more quickly than the crude kerosene.

Bilharzia Hæmatobia in Cyprus.—Dr. George A. Williamson of Cyprus contributed this paper, the interest attaching to which was the record of the fact that bilharzia was found in the urine of a man who had never been out of the island of Cyprus. When admitted to hospital his urine was found to contain numbers of typical bilharzia ova, frequently embedded in a man of red blood corpuscles. Not only were the characteristic ova found, but the ciliated free-swimming embryo was observed to develop from the ovum when water was added to the urine. Although bilharzia have been found in Mesopotamia and in Arabia, they were the only countries outside of Africa in which the parasite had been proved to exist; now Cyprus must be added to the list.

Friday, August 1.—Third Day.

Yellow Fever.—Mr. James Cantlie of London opened a discussion on yellow fever by a review of what recent researches, more especially by the United States Army Commission in Cuba, had brought to light in connection with this disease. The Commission had proved. (1) That blood taken from a yellow-fever patient, and injected into a non-immune person would cause yellow fever; (2) That the blood could produce this effect whether fresh, defibrinated, or diluted, and passed through a Berkefeld filter; (3) That no bacillus is found in the blood of yellow-fever patients; (4) That the specific agent which causes yellow fever is attenuated or destroyed by exposure to a temperature of 55° C. for ten minutes; (5) The mosquito-stegomyia fasciata is responsible for the spread of yellow fever, serving as the intermediate host; (6) After the mosquito has fed on a yellow-fever patient, twelve days must intervene before its bite can infect; (7) Mosquitos have been proved to be capable of conveying yellow fever by their bite up to fifty-seven days after feeding; (8) Infection by contact with the sick, as in nursing yellow fever, does not expose the nurse to danger; (9) Infection of fomites does not take place. The conclusions gathered from these experiments and observations were: That either the specific agent of yellow fever is ultra-microscopic, or that there is no bacillus or other germ present in the blood. Analogy would teach us to believe, however, that the specific agent in yellow fever is a germ and not a toxin. Were a toxin the cause, it is difficult to conceive why the intermediate host—the mosquito—must harbor the parasite for twelve days before the bite is effective. This fact would seem to indicate that the specific agent is a germ and not a toxin. Mr. Cantlie drew attention to the possibility of yellow fever existing elsewhere than in the West Indies, and the west coast of Africa. He drew attention to the diseases "acute yellow atrophy," "bilious remittent fever," especially to the "typhus bilieux" in Egypt, which, in the early part of the nineteenth century, when Napoleon occupied Egypt, was known of under the name of yellow fever—fievre jaune.

The Differential Diagnosis of Yellow Fever and Malignant Malaria.—Dr. George C Low contributed this paper. In certain islands of the West Indies, when an outbreak of fever occurred, some doctors would diagnose the ailment as malarial, others as yellow fever. The diagnosis, therefore, was not, in the early part of the outbreak of yellow fever, always easy. Reliance could not be placed on the facial expression, on the condition of the tongue or the skin, on the early appearance or delay of jaundice.

The relation of the temperature to the pulse was of some importance; in yellow fever the pulse showed while the temperature was yet high; in malaria this was not observed. The early appearance of albuminuria in yellow fever was not a sufficiently distinctive feature to be relied upon, as the same occurred in malarial infection. Epigastric pain or vomiting, so frequently described as characteristic of yellow fever, were not confined to cases of this disease, nor was hæmaturia, which occurred in both diseases. The blood examination was the only reliable method of determining the question of differentiation between yellow fever and malaria; but it was possible that the malarial parasites might be present in the blood of a person suffering concurrently from yellow fever. Gray of St. Lucia has lately made differential counts of the leucocytes and found in several cases of yellow fever that the large mononuclear leucocytes were normal, whereas in malaria their increase formed a diagnostic point. Postmortem, the presence of malarial pigment, parasites in the brain, spleen, or gastric mucosa at once pointed to malarial infection.

Malta, or Mediterranean Fever.—Dr. P. W Bassett-Smith and Staff-Surgeon R N. Haslar contributed a paper entitled "The Agglutinating Properties in the

Blood In Cases of Mediterranean Fever, with Special Regard to Prognosis. Remarks on Other Blood Changes and Reactions During the Course of the Disease." The cases seen by the authors during the past two and a half years numbered 196.

The technique employed consisted in using an emulsion made from a five-day old agar culture of the micrococcus in saline solution. This was drawn up into sterile pipettes and killed at 65°C. for a period of fifteen minutes; the same series of pipettes being utilized throughout in the cases. The blood was centrifugalized and the serum generally employed a few hours after it was obtained. The dilutions were made with a measuring pipette as recommended by Wright, an equal part of diluted serum (20 c.mm.) and emulsion being always used, so that the number of organisms present in each sedimentation tube was approximately the same in each instance. These were left at room temperature for twenty-four hours and the results recorded, the dilutions ranging from 1 to 20 to 1 to 2,000.

From a study of the clinical characters of the cases and the agglutination curves, the author found that the high agglutinating power of healthy convalescents slowly fell again, but reacted to 1 to 100 or less for months. In debilitated convalescents, there was no rise.

As regards prognosis, it was found: (1) High sustained agglutinations in the early stages of the fever were favorable; (2) A continuation of low agglutinations during the whole course of the fever following cachexia was bad, the cases dragging on for years with recurrent attacks of slight fever and the neuroses so difficult to cure; (3) A continuous rise with improving clinical symptoms indicated approaching convalescence; (4) As a rule, there was no relation of the agglutination curve with that of the fever. Mediterranean fever had been diagnosed in sailors returning from China.

Men who have once had the fever should not return to the endemic area for some time, the bactericidal power of the serum against the specific organism of Mediterranean fever being very slight.

In Malta fever the hydræmic condition of the blood was very apparent. The red cells were markedly diminished, the white were often relatively increased, the relative preponderance of the mononuclear basophylic cells being marked.

The Geographical Distribution of Malta Fever and the Value of Splenic Enlargement as a Test of Malarial Incidence.—Dr. James A. Hislop of Assam contributed a paper with this title. After referring to the many regions of the tropics or the tropical countries from which Malta fever has been reported of late years, Dr. Hislop remarked that he had met with cases closely resembling Malta fever in Assam. It would appear that in Assam there occurred a fever which resisted quinine, yet is accompanied by great enlargement of the spleen. It appeared certain that fevers other than malaria caused enlargement of the spleen. The generally-accepted doctrine that any uncomplicated fever lasting more than six days and resistant to quinine properly given is not malarial, required to be modified in view of recent observation and experience.

Kala-azar, an Analogous Disease to Malta Fever.—Dr. Charles A. Bentley of the Borjeilie Tea Estate, Tezpurp, Assam, sent a communication with this title. Kala-azar had at different times been considered as the result of ankylostomiasis (Giles); as a very intense form of malarial fever (Rogers); post-malarial cachexia (Ross), etc. In eighteen months Dr. Bentley had seen and treated some 400 cases of kala-azar, and from a study of the disease he had come to the following conclusions: (1) Kala-azar was neither malarial fever, benign or malignant, nor was it any form of malarial cachexia or post-malaria cachexia. It might, however, be complicated by a coincident malarial infection; (2) Kala-azar was a distinct disease, of which the first and second stages had been described by Ross, in which an initial attack of irregularly intermittent, remittent, or continued fever was followed by recurrences of a similar nature in the first stage; and the second stage of nearly continuous fever of a low type; together constituted the whole of one febrile affection of long duration.

The application of the three methods of diagnosis, namely, periodicity, the therapeutic action of quinine, and the blood examination, showed that kala-azar failed in all three to justify its being considered a malarial infection. As justifying the connection between kala-azar and Malta fever, it was found that, clinically, they closely resembled each other, the micrococcus melitensis had been found in cases of kala-azar, and the result of the serum test appeared absolutely to prove the identity. It was true the death rate in kala-azar was abnormally high, whilst in Malta fever it was quite low; but in Assam, where persons contracted kala-azar, they were reduced to so low a state of poverty that death might be due to their feeble state.

Dr. Manson, in discussing the subject, related his experience of the unreliableness of cultures of the micrococcus melitensis as found in the clinical laboratories of London, and warned observers against relying too implicitly on deductions based on results obtained with the cultures in use in India.

Statistics of the Blood Examination in Cases of Malaria in Cyprus During a Period of Twelve Months.—Dr. George A. Williams of Cyprus contributed a paper on this subject. It was found that in 94.4 per cent. of cases diagnosed as malaria parasites existed in the blood. The percentage of the different varieties of blood parasites in reference to the total number found in malarial cases were: tertian, 48.46; quartan, 8.03; estivo-autumnal, 43.50.

Treatment by hypodermic (intramuscular) injections of quinine had proved most efficacious. The acid hydrochloride of quinine was used, and the smallest dose given for an adult was 3 grains night and morning for three days. The largest single dose given in any case was 10 grains, and the usual dose 5 grains night and morning for three days.

Heat Apoplexy.—Dr. Edward Henderson, late of Shanghai, China, read this paper. He divided the cases into those in which (1) exhaustion with a normal or lowered temperature, with little or no loss of consciousness, and (2) those in which a high temperature and more or less complete loss of consciousness are the distinguishing characters. In the latter variety had been assigned the names of thermic fever, siriasis, and heat apoplexy. The form of this condition, seen by Dr. Henderson, was one in which "a hyperpyrexia was closely connected with exposure to heat, and the appearance of the patient was that of a man suffering from apoplexy." The cases met with were amongst the foreigners in Shanghai, but there was reason to believe that the condition was also met with amongst the Chinese population. Sudden attacks of high temperature in children would seem to indicate that they were not exempt from heat apoplexy. Alcohol played an important part in this disease amongst adults, and the death rate was very high in alcoholics. Dr. Henderson showed photographs of a special couch he had devised for the treatment of cases of heat apoplexy and hyperpyrexia by the "cold douche." Heart failure was the ultimate cause of death in heat apoplexy.

The Prophylaxis of Sunstroke.—Lieut.-Col. Andrew Duncan, I.M.S. (retired), read a paper on this subject. The actinic and not the heat rays of the sun were the active agents in producing sunstroke. He said experience had taught him that an orange-yellow covering to the body would counteract the effect of the actinic rays, and during a trial of five years he had found wearing an orange-yellow shirt, lining the helmet with orange-yellow flannel, and the same material stitched inside the coat over the spine, afforded a very efficacious means of prophylaxis.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting Held May 14, 1902.

Primary Carcinoma of the Vermiform Appendix.—Dr. D. S. D. Jessup read this paper (see page 289).

Smallpox.—Dr. S. Pollitzer demonstrated a series of lantern slides illustrating the gross and microscopical lesions of variola.

Dr. James Ewing presented a review of a study of vaccine bodies in variola, and of the results of bacteriological examination, by ordinary methods, of cadavers of twenty-nine cases of variola. Vaccine bodies were studied in the cutaneous and visceral lesions of variola by a variety of methods. In the fresh condition the fluid from the cutaneous lesions at various stages was examined, unstained, and stained by gentian violet. By this method many leucocytes and epithelial cells and many red cells could be distinguished and set aside. The sporocysts described by Funck (*British Medical Journal*, 1901, I, p. 448), seemed to correspond to certain large cells containing one or many greenish refractive globules. In stained smears these resolved themselves into vacuolated leucocytes and epithelia. Myriads of fine granules were usually present, which stained like protoplasmic detritus. The typical vaccine bodies were larger, spherical, homogeneous, or translucent bodies, colorless or yellowish, with or without membranes, from one to seven inches in diameter. Many were extra-cellular, some within other cells. Treated with gentian violet the membranes about many of them became distinct. By this and other staining reagents the bodies exhibited certain polychromatic tendencies, varying toward distinct basophilia. The resemblance of many of the polychromatic bodies to the red cells in the pustules which were undergoing subdivision with loss of distinct acidophile staining suggested that many of the vaccine bodies might be derivatives of red cells. The bodies with membranes, and the small crescentic forms especially, seemed to have this origin. In stained specimens some of the bodies stained blue, some red, some red on the periphery and blue in the center. These latter forms resembled the polychromasia which Maragliano described in circulating red cells. The speaker failed to find any traces of amœboid movements in many specimens examined on a warm stage. In sections of the skin and mucous membranes, the main fact elicited was that the vaccine bodies were usually present in the lesions in all stages up to complete healing. They were not always present in the early necrotic foci of the tracheal and œsophageal mucosa. The forms of the bodies encountered included all of those described at length by Huckel. The bodies appeared in large numbers in the skin and mucous membranes in the petechial spots of a case of variola with ulcerative endocarditis, dying in the third week of the disease. In some of these spots, however, only fragmented acidophile red cells appeared. They were unusually abundant in a case dying in the late pustular stage, in which fresh hemorrhage occurred into the pustules (black smallpox). The abundance of the bodies seemed to bear a constant relation to the severity of the disease, and especially to the hemorrhagic character of the lesions. In the well-developed early pustule they were most numerous in the large flat cells on the outskirts of the necrotic zone. In the necrotic zone they were less numerous, were often found disintegrating and granular, and distinguished with difficulty. They were seldom numerous in the foci, exhibiting most active degeneration. In the early stages of necrotic lesions of the trachea many foci were found in which vaccine bodies were absent. The impression was therefore gained that if the variolous poison came from these bodies it was distributed in a most erratic manner. Infected cells must certainly long remain alive, and in some healing lesions it seemed equally certain that many infected cells would not suffer permanently from the presence of the body. In necrosing cells the bodies were found to vary in size, to appear as rosettes, crescents, rods, and finally to break down into fragments, sometimes with vacuolation, along with the cytoplasm of the harboring cell. Sometimes the necrosing cells become condensed and present an appearance recalling that of some sporocysts. In the necrosing epithelium of the cornea, conjunctiva, and nictating membrane of healthy dogs, Dr. Ewing failed to find any structures resembling vaccine bodies.

The distribution of vaccine bodies was found to be coextensive with the lesions of the disease, whether these were of the strictly variolous focal type or induced by secondary bacterial invasions. They were found in the cutaneous lesions of the pharynx, epiglottic folds, in the ulcerated nasal and ethmoidal sinuses, very abundantly in the trachea and bronchi, in the œsophagus, in the circumscribed or diffuse ulcerations of the stomach, abundantly in the intestine, and in the renal pelvic epithelium.

Various lesions of the skin and mucous membranes were examined to determine if vaccine bodies were present in other than variolous processes, and while never finding in any other lesion a great abundance of bodies resembling the vaccine corpuscles, Dr. Ewing found a scanty or moderate number of structures indistinguishable from vaccine bodies in streptococcus inflammation of the skin, in erysipelas, in pemphigus, in dermatitis herpetiform, in purpura hæmorrhagica, and in measles. In the decaying skin of variola the vaccine bodies disappeared without sign of multiplication between the fourth and eighth days.

Some vaccine bodies seemed to give evidence of an origin from the cytoplasm of the epithelial cells. This was especially true of those bodies which were connected with the cytoplasm of the cell by radiating fibers, and of those forms which exhibited a central basophile mass fringed by a peripheral acidophile portion. Yet the smallest and presumably the earliest vaccine bodies did not exhibit these radiating threads, but were extremely well-defined from the cytoplasm, and impressed the observer as being distinctly foreign to the cell. Hückel had some difficulty in adjusting his theory of a cytoplasmic origin to the appearance of these small compact bodies. The speaker's belief that many of the typical vaccine bodies in human tissues were remnants of red cells had been reached very slowly. It first appeared in the study of human material that vaccine bodies were most numerous in the hæmorrhagic lesions, and that by some stains, *e. g.* Heidenhain's iron-hæmatoxylon, the vaccine bodies behaved very much like red cells. Distinct transitional stages between red cells and fragments and basic vaccine bodies were not encountered until late in the series, when a trachea, which had been hardened in Orth's fluid (Muller-formalin), exhibited a great variety of forms, which resembled red cells in their tendency to stain with eosin more than the usual vaccine body. In the late secondary hæmorrhagic case, in which recent profuse hemorrhage had occurred into the pustules, a great variety of forms, apparently transitional between red cells and vaccine bodies, were found in and between epithelial cells. Finally, in the renal pelvic epithelium of two primary hemorrhagic cases was encountered a profuse display of the englobement of red cells and their fragments by epithelia, and their transformation into polychromatic vaccine bodies. Here were found red cells unaltered, within and between epithelial cells—large red cells with beginning or advanced vacuolation, some strongly acidophile, some strongly basophile; all sizes of acidophile fragments; some epithelial cells holding within the same vacuole various shades of acidophile and basophile fragments of red cells; englobed red cells with basophile centers and acidophile peripheries; or fragments fringed with protoplasmic or hæmatoidin granules. These polychromatic qualities were best demonstrated by staining with strong hœmatein and strong watery eosin. With dilute eosin most of the bodies remained tinged with hœmatein. By methylene blue or Nocht's method the bodies usually stained light or dark blue. Their perinuclear position and distinct halo were identical with those of the typical vaccine body of the cornea

The above observations, which were readily duplicated by a review of the previous material, seemed to place beyond doubt the conclusion that red cells might be, and very frequently were, transformed into bodies indistinguishable from vaccine bodies. Yet in specimens fixed by Muller's or Orth's fluid, strong staining in watery eosin developed a certain acidophile tendency in many of them, although leaving the nuclei of epithelia and leucocytes uniformly dark blue. The belief that many vaccine bodies were derived from red cells accorded with many facts concerning the occurrence of these bodies and the changes which might affect red cells. Two familiar types of degeneration of red cells occurred in the circulating blood in various conditions, especially in cases of severe streptococcus infection. They were: (1) Polychromasia of Maragliano, in which a central basophile portion of the red cell separates from a broad peripheral portion containing all of the hæmoglobin remaining in the cell; and (2) Polychromasia of Gabrichevsky, in which the entire cell stains a brownish color after treatment with eosin and methylene blue or eosin and hæmatoxylon. Punctate basophilia and schistocytosis, or subdivision of red cells with the appearance of basic centers of the fragments, also frequently occurred in the circulating blood. A pronounced case of this latter type had been described by K. Ehrlich and Lindenthal (*Zeitschrift fur klinische Medicin*, Bd. 30, p. 427), in nitrobenzol poisoning. The basophile portion was regarded as the remnant of nuclear material in the red cell Now, all of the above changes in the red cells occurred in very unusual abundance in and about the focal lesions of variola and vaccinia. In the earlier stages of the lesions the necrosing tissues and their vicinity were literally drenched with fragments of subdivided red cells exhibiting various polychromatic staining qualities. The speaker had seen no other type of lesion in which such active destruction of red cells occurred about necrotic foci. Hence, about the inflamed cells of the variolous lesion of epithelium there was a great abundance of already altered fragments of red cells, which, when englobed by the epithelia, at once possessed the characters of vaccine bodies. The somewhat specific quality of this destruction of red cells about the variolous lesion might explain the abundance of vaccine bodies in such foci, which was practically a pathognomonic feature of variola.

The perfectly homogeneous quality of the majority of vaccine bodies had suggested that they represented a form of hyaline degeneration of the cytoplasm; but the sudden appearance of these compact masses in the cytoplasm of epithelia had distinctly impressed the minds of most observers, including Hückel, with the idea that they must be bodies foreign to the cell. The granular edges of some of the bodies might be referred to the disintegration of the outer rim of the red cell, while the pseudopods of vaccine bodies were identical in appearance with the knobs on shrinking and deformed poikilocytes. Sometimes there was a rim about the compact vaccine body, such as existed also about hardened and densely-stained fragments of red cells. The occurrence of hematoidin granules about the halos of some vaccine bodies was an unusual but unmistakable suggestion of the true origin of these particular individuals.

While it seemed certain that many bodies passing as probable parasites were remnants of red cells, before attempting to extend this theory of origin to all vaccine bodies it was clearly necessary to demonstrate such a relation for the vaccine bodies in the corneal epithelium. Here, in a bloodless tissue, it seemed hardly possible that red-cell detritus could account for the great numbers and comparatively wide distribution of vaccine corpuscles. Hence the theory of the existence of a specific form of vaccine body, possibly parasitic, remained almost untouched. That the vaccine bodies of the cornea were not derived from red cells forced into the epithelium from the lymph spaces communicating with the canal of Schlemm, was practically certain, because these lymph spaces in corneal vaccinia, at least in the centers of the cornea, were usually free from red cells. Another possible mode of origin was from the abundant red-cell detritus of vaccine, which might account for the bodies seen in one inoculation wound, but Vasielevski claimed to have transferred vaccine from cornea to cornea through forty rabbits, finding the vaccine bodies undiminished in each case. These results, if correct, would indicate that the corneal vaccine body was either a parasite, or, as Huckel believes, a derivative of the epithelial cell.

Considering the very peculiar conditions of nutrition of the corneal epithelium pointed out by Ranvier it might very well be that entirely different processes took place in these cells and in vascular human tissues, and that the vaccine bodies of the cornea were entirely different from those of other tissues. Against this possibility was the very great similarity between all typical vaccine bodies; while the results of the present study still further complicated the subject by indicating that red-cell detritus might assume forms apparently indistinguishable in position, morphology, and staining reactions from typical vaccine bodies. Possibly some method might be secured by which one could distinguish red-cell detritus from vaccine bodies; or, on the other hand, some facts might be gathered pointing to the possible access of red-cell detritus to the corneal ulcer.

Studies on the Etiology of Vaccina and Variola.—Dr Anna W. Williams said that the studies reported in Dr. Ewing's paper might be divided, according to the methods employed, into two parts: (1) bacteriological and (2) histological. The direct object of the bacteriological studies had been to determine if an organism in pure cultures could be obtained which would produce typical vaccina or variola, while that of the histological studies had been to determine the nature of the "vaccine bodies." In the bacteriological studies the plan of work was as follows: (1) Studies of serial and isolated smears and hanging drops from eruptions on rabbits, calf, monkey, and man, from corneas of rabbits, from fresh and old glycerinated vaccine virus, and from filtered lymph. (2) Cultures made from all of these materials, but especially from the inoculated corneas of rabbits and old glycerinated vaccine virus, using ordinary and special media. The ordinary media were used as controls. The special media used were (1) Ascitic-broth, ascitic-broth in celloidin capsules inserted into the peritoneal cavity of the rabbit; (2) Wounded peritoneum and subcutaneous tissue of vaccinated and non-vaccinated rabbits; (3) Rabbits' skin in the peritoneal cavity of the rabbit; (4) Fetal rabbits' skin taken with aseptic precautions; (5) Fertilized hens' eggs.

The most interesting results were obtained from the inoculated rabbit corneas. These experiments were still in progress. The technic was as follows: The corneas were inoculated with old glycerinated virus and after a varying time the animals were killed, the eyes removed under aseptic precautions and washed in sterile broth. The whole cornea was then cut out, washed in successive sterile broths, placed on an agar plate, and kept at 36°C. over night. If there was no apparent growth the next day, the cornea was placed in ascitic broth, after smears and hanging drops had been made from the inoculated area, and returned to the thermostat. After twenty-four hours much of the epithelium had become loosened and on shaking, the ascitic broth became slightly cloudy with apparent irregularly granular detritus. Microscopically, besides much finely granular material there were seen a few vaccine-like bodies free, and many epithelial cells and leucocytes in various stages of degeneration, some of the former still containing "vaccine bodies." The ascitic broth containing these cells, "vaccine bodies," and granules, when rubbed on freshly-shaved rabbit's skin produced a typical eruption.

The chief points of interest in this cultural study of the corneas were (1) That it had given us a method for obtaining active vaccine virus unmixed with discoverable organisms, and (2) That it showed that vaccina is not produced by an organism or a combination of organisms growing readily in ascitic broth.

The histological studies were made principally upon rabbits' corneas. The sections were prepared by Dr. Flournay. Control inoculations were made with (1) Inactive vaccine virus; (2) Filtered vaccine virus; (3) A very large coccus isolated from vaccine lymph and having forms similar to many of the vaccine bodies; and (4) The tiny bacillus; and (5) the large coccobacillus spoken of in the first part of the paper.

From the study of the corneal sections it was shown that: (1) The epithelial cells of the cornea might be phagocytic for leucocytes, red-blood cells, certain bacteria, and variously shaped and sized chromatin-staining bodies, the so-called "vaccine bodies"; (2) Apart from the above inclusions, certain degenerative changes might appear in the epithelial cells; (3) All of these appearances were most frequently seen in the perinuclear zone; (4) The "vaccine bodies" appeared regularly after inoculations of active vaccine or variolous lymph; they did not appear after inoculations of any other substance tried.

The principal observations from these studies might be summarized as follows: (1) The specific virus of vaccina grows readily in the corneas and the skin of rabbits, producing in the latter situation the typical eruption; (2) Ascitic broth containing the epithelial cells from corneas which have been inoculated with old active vaccine lymph produces the typical eruption of vaccinia, though no organisms can be demonstrated in the ascitic broth mixture; (3) Such corneas show as the only constant characteristic appearance the so-called "vaccine bodies"; (4) Vaccina is not due to any organism or combination of organisms, growing readily in ascitic broth.

Dr. Ewing said that the contribution just read showed evidence of such a volume of work conducted on such a judicious plan that he felt that Dr. Williams and her colleagues were to be congratulated upon it. It was a specially important result that Dr. Williams was able apparently to demonstrate an increase of the virus in ascitic broth to which infected corneas had been transferred. Regarding the isolation of various bacteria from vaccine and variola, it was to be noted that one was in the habit of casting aside as unimportant cultures which were occasionally encountered, but it might well be that some of these demanded further attention; and although previous work in this field had been extensive, it still remained important thoroughly to test as many of these species as possible. The great difficulty of determining the presence or absence of specific effects from such bacteria had led to many erroneous claims for bacteria occasionally occurring in vaccine and variolous exudates. He had had some experience with these difficulties with a bacillus, which he called Bacillus 19. It resembled in morphology and in the fluidification of blood serum, that described by Martin in 1893. A calf was tested with this bacillus. Vaccination with Bacillus 19 was negative, and a culture was injected subcutaneously, producing an abscess from which after two weeks the germ was recovered pure. The first attempt to vaccinate this calf with active vaccine failed, but a subsequent vaccination made very thoroughly produced a "dry take." From this "dry take" a second calf was vaccinated also with an unsatisfactory "dry take." Both of these calves were vaccinated the second time, and each gave as good a take as after the first vaccination. These results on the calves being unsatisfactory, the bacillus was finally set aside when it was proven inert on monkeys.

Experiments with Filtered Vaccine.—Dr. William H. Park said that, as was well known, attempts to produce a vaccination with the fluid which had passed through a Chamberland or Berkefeld filter had uniformly failed. The present experiments were undertaken with the idea of using crushed virus and of concentrating the filtrate. It was thought to be conceivable that the vaccine organisms might be small enough to pass through the filter and still, because of being contained in the epithelial cells, they might not pass, the cells themselves being held back. It was also thought possible that the filtrate might contain a few vaccine organisms, and yet have an insufficient number to cause a vaccination. If this condition existed, it seemed possible that by quickly evaporating the filtrate, sufficient concentration of virus might take place to produce vaccination. The following experiments were tried: Fresh virus was dried over sulphuric acid in a vacuum. This vaccine material was crushed up with fine sand, using a pressure of twenty-five tons to the square inch. This material was rubbed up with water and separated into two portions. One was drawn through a Chamberland filter, the other through a Berkefeld filter. Both filtrates were evaporated over sulphuric acid in a vacuum. Calves and rabbits inoculated failed to take. Similar virus was crushed with the sand twice, and again six times. The filtrate from this material failed to take. Ordinary glycerinated vaccine and active serum from calves were filtered and failed to take in calves or rabbits. All these calves were kept in a special building belonging to the Department of Health where no possible contamination could occur. Three calves treated in the same way in the vaccine building developed a few typical vesicles, but these are believed to have been due to contamination from the other calves and not to substances which passed through the filter.

The Relation of Streptococcus Pyogenes to Variola.—Dr. James Ewing said that from the routine bacteriological examination by ordinary methods of the cadavers of twenty-nine cases of smallpox, the streptococcus pyogenes was demonstrated in the heart's blood in all cases, and in the cutaneous lesion of about ninty per cent. of the cases. This result with the heart's blood was only in accord with the results of some previous studies, as Le Dantec (Arch. de Med. Navale T. 64, p. 410) obtained the streptococcus in the heart's blood of fifty consecutive cases. The abundance of the growth was uniformly proportional to the severity of the disease, and in the primary hemorrhagic cases the cultures were remarkably profuse. In two cases the streptococcus was associated with the Klebs-Loeffler bacillus, in subjects exhibiting extensive tracheal diptheria; and in two cases dying late in the disease, with much ulceration of the skin, staphylococcus aureas also grew. Once a special bacillus, called "Bacillus 19," was also obtained. In five cases, cultures of ten c.c. of circulating blood were examined with a negative result. Only one of these cases was fatal. Arnaud, however, had reported finding the streptococcus in the circulating blood in two primary hemorrhagic cases (*Revue de Med.* 1900, p. 303). The demonstration of streptococcus in the cutaneous lesions in nearly ninety per cent. of the cases indicated the very general presence of this organism in these lesions. Perhaps more careful technique would have given more uniform results, as chain cocci were twice found in sections of the skin when cultures were sterile. Most of the autopsies were performed within one to six hours after death, and while there was opportunity for post-mortem development in some cases examined after a longer interval and in hot weather, the usual abundance of the streptococcus did not fail in early autopsies in very cold weather. The uniform presence, and especially the remarkable abundance of the streptococcus in these cases seemed paralleled in no other conditions except in scarlatina and peurperal septicæmia, while the histological lesions indicated widespread effects of the growth of this microorganism similar to those of pure streptococcus infection. This was especially true in the primary hemorrhageic cases in which the bacteriological and histological study of the cadaver strongly indicated that the streptococcus overshadows any other microorganism that might be present. These conditions led the speaker to conclude that it would always remain impossible to reproduce the fulminant type of variola without the aid of this microorganism. When the streptococcus was present in the circulating blood in enormous numbers and on the second or third day of a disease, the question naturally arose whether the presence of this microorganism in the disease should be classed as a simple secondary infection. Nevertheless, the known facts did not warrant the assumption of a necessary symbiosis because vaccine produces specific lesions when no streptococci can be demonstrated in the virus. The condition seemed very nearly like those described by Schleich as "syntoxic parasitism," although present indications favored the belief in a microorganism too small to be seen with the microscope rather than in the purely chemical nature of the specific virus or smallpox. A further review of the clinical features of smallpox demonstrates other interesting relations of the streptococcus to the disease. In two cases, general scarlatiniform eruptions developed during the course of ordinary discreet variola. One of the patients died in a children's ward in which no further cases of this sort developed. The other went through the usual course of scarlatina with profuse scaling desquamation, but later developed multiple abscesses in the skin. These were therefore probably not cases of true scarlatina, but examples of the scarlatiniform septic eruptions due to the streptococcus which was abundantly present in both. Three cases of ulcerative endocarditis were encountered with the usual abundance of streptococci in the heart's blood. One of these gave cardiac symptoms from the first and died on the eighth day with extensive ulceration of the mitral valve and a rather scanty eruption. Finally, erysipelas and diffuse phlegmonous inflammation of the skin were very common incidents in smallpox hospitals. In these various clinical features of the disease the streptococcus exhibited its well known capacity to produce a great variety of specific clinical effects, and in them it seemed to follow the ordinary rules governing secondary infection. In these clinical forms of the disease it was interesting to note how this microorganism could multiply in the system; first, as a complicating factor in the cutaneous lesion of smallpox then as the excitant of a scarlatiniform eruption, then, under the form of pyæmic abscesses, or as ulcerative endocarditis or erysipelas, etc., while none of these manifestations seemed to confer any immunity to the subsequent attack of the microorganism in another clinical form.

Dr. Park said that Dr. Ewing had demonstrated that in a large series of fatal cases streptococci were universally present in the blood and in the postules of the skin and mucous membranes. It seemed to him that he went too far, however, in thinking that the streptococcus was necessarily present before the symptoms and lesions in smallpox could develop. Both scarlet fever and smallpox caused marked changes in the mucous membranes of the throat: here streptococci were regularly present. The profound changes produced by the poison of variola combined with the location of the streptococci seemed to account sufficiently for the secondary infection of the streptococcus. If no streptococci existed, there would still be severe andprobably fatal cases of smallpox.

Dr. Ewing said his own ideas regarding the relation of the streptococcus to variola were by no means clear, but he had been greatly impressed with the very early appearance and enormous development of the streptococcus in the disease. Its behavior in the pirmary hemorrhagic cases, and in some other forms, seemed different from that of an ordinary secondary infection. He did not find either that the term "symbiosis" was justified by the facts. It would seem that the smallpox virus annihilated resistance to the growth of the streptococcus, with results which occasionally resembled fulminant puerperal septicæmia, in which the streptococcus was the only microorganism present. Perhaps Schleich's term "syntoxic parasitism," most closely expressed what seemed to be the condition in primary hemorrhagic smallpox. As to the relation of red cells to vaccine bodies, he was not prepared to claim that all vaccine bodies were derivatives of these cells, but having found that in the tissues the fragments of red cells were a very common origin of vaccine bodies, he was inclined to think that all vaccine bodies might have the same origin. In the cornea it seemed almost hopeless to attempt to prove this origin, in which case the theory of the exclusive origin of vaccine bodies from red cells must have falied of demonstration. He had already found that red cells were present in the inoculation wounds of the cornea under somewhat surprising conditions. Therefore, considering all the evidence against the parasitic nature of vaccine bodies, at a time when some Continental observers are grouping carcinoma and variola together, it seemed justified to urge that some and possibly all of the appearances on which this relation is based were referable to red cell detritus.

Clinical Theory of Smallpox.—Dr. W. S. Magill read this paper. He detailed results which he had obtained by the chemical separation of alkaloidal and diastatic substances from vaccine pulp and from glycerinated virus and the injection of these substances into animals.

Books Received.

The Practical Medicine Series of Year Books, Vol. VII. By Gustavus P. Head, M.D. 12mo, 270 pages. The Year Book Publishers, Chicago, Ill. Price, $1.50.

Manuel D'Histologie Pathologique. By V. Cornil et L. Ranvier. 8vo, 864 pages. Illustrated. Vol. II. Felix Alcan, Paris, France. Price, Fr. 25.

Die Anatomie und Physiologie der Kehlkopfnerven. By Dr. A. Onodi. 8vo, 179 pages. Oscar Coblentz, Berlin. Price, Mr. 6.

Kurzes Lehrbuch der Krankheiten der Oberen Luftwege. Von Prof. Dr. Holger Mygind. 8vo, 252 pages. Illustrated. Oscar Coblentz, Berlin. Price, Mr. 6.

Diagnostic Gynecologique des Organes Genitaux et de la Mamelle. Par Le Docteuer Clado. 12mo, 821 pages. Illustrated. Paper. A. Maloine, Paris.

La Guerison de la Morphinomania sans souffrance. Par Le Dr. Oscar Jennings. 12mo, 231 pages. A. Maloine, Paris.

The Schott Methods of the Treatment of Chronic Diseases of the Heart, with an Account of the Nauheim Baths, and of the Therapeutic Exercises. By W. Bezlythorne, M.D. Fourth Edition. 8vo, 138 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $2.00.

The Medical Student's Manual of Chemistry. By R. A. Witthaus, A.M., M.D. Fifth Edition. 8vo. 678 pages. William Wood & Company, New York. Price, $3.50 net.

International Clinics: a Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and Other Topics of Interest to Studbnts and Practitioners. By various authors. Edited by Henry W. Cattell, A.M., M.D. Vol. II. Twelfth Series, 1902. 8vo, 295 pages. J. B. Lippincott Company, Philadelphia, Pa.

A Text-Book of Practical Therapeutics. Ninth Edition. By Hobart Amory Hare, M.D. 8vo, 857 pages. Illustrated. Lea Brothers & Co., New York. Price, cloth, $4.00; leather, $5.00; half-morocco, $5.50 net.

A Brief of Necroscopy and Its Medico-Legal Relation. By Gustav Schmitt, M.D. 16mo, 168 pages. Funk & Wagnalls Company, New York. Price, $1.00 net.

Atlas and Epitome of Abdominal Hernias. By Georg Sultan. 12mo. 277 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price, cloth, $3.00 net.

Treatise on Diseases of the Skin. By Henry W. Stelwagon, M.D. 8vo. 1115 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price, cloth, $6.00 net; half morocco, $7.00 net.

New Instruments.

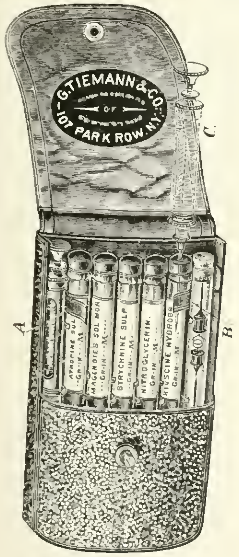
A CONVENIENT POCKET HYPODERMIC CASE.

By A. S. TAYLOR, M.D.
NEW YORK.

VISITING SURGEON TO RANDALL'S ISLAND HOSPITAL; ASSISTANT INSTRUCTOR IN OPERATIVE SURGERY AT COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK

The many inconveniences and the loss of time associated with the use of hypodermic tablets are known to every practising physician. When solutions are kept in stoppered bottles, there is also much inconvenience and the solutions are exposed to contamination. During my ambulance service at the New York Hospital in 1896 there was evident necessity for accessible and sterile hypodermic solutions, which could be used with the ambulance in motion. At that time Mr. Rauschenberg, the hospital chemist, suggested to me the use of solutions in sterilized vials covered by sterilized rubber caps, the working of which will be later explained.

Their use on the ambulance was so satisfactory, that the same system was soon introduced into the wards and operating rooms of the hospital. The pocket case is simply an adaptation of the same principle, and was made by G. Tiemann & Co. The essential idea consists in having the solution in a rubber-capped vial. (All sterilized of course.)



G. TIEMANN & CO.
107 PARK ROW, N.Y.

MAGENDIES SOL MOR ···GR·IN···M····
STRYCHNINE SULP ··GR·IN···M·
NITROGLYCERIN. ··GR·IN ·M·
HYOSCINE HYDROBR GR·IN··M·

The case is made of leather with metal lining in the back and sides. Metal clips are fastened to the back to hold the syringe and vials. On one side is the syringe and on the other is a sterile glass tube containing two sterile needles. Just beneath each of these is a leather strip (A and B) to facilitate its removal from the case. Between the two are five rubber-capped vials, each holding 100 m. of solution. The solutions may vary in strength and variety to suit the needs of the individual practitioner.

The case, as a whole, is curved transversely, so as to fit the body nicely when it is slipped into the vest pocket.

In using the case the needle is screwed onto the syringe, the case is inverted (see figure), the needle is thrust through the rubber cap of the vial containing the desired solution (c), the prescribed dose is drawn down into the syringe, and the needle is withdrawn from the vial ready for use. (The rubber caps may be kept sterile by laying a pad of sterile gauze over them in the case, or by wiping them with a one-per-cent. formaldehyde solution, alcohol or bichloride, just before using them. In an emergency these precautions may be omitted with but very slight risk). The elastic recoil of the rubber serves to close the puncture and prevent leakage.

The advantages of the case are:

1. Ease and speed in giving a hypodermic injection. For operations the needle may be screwed to the syringe, the syringe fastened in its clip, and the case put in the anæsthetist's pocket ready for instant use.

2. The presence of an ever-ready sterile solution and sterile needle. The five vials allow sufficient variety in the solutions to meet any emergency. The solutions will keep intact for months in the vials, as proven by tests. (Magendie's solution of morphine may become yellowish and is then unfit for use.)

3. The vials may be easily filled by any pharmacist who understands the principles of aseptic work.

During the last five years the method has been used throughout the New York Hospital, and hypodermic abscesses have become unknown.

152 West Fifty-seventh Street.

Surgical Suggestions.

Surgical Treatment of Pruritus Vulvæ.—Tavel advocates resection of the internal pudic nerve in obstinate cases of vaginismus and pruritus of the vulva, and reports two cases in which he applied the treatment with good results. The external incision on either side of the perineum, which is about four inches in length, is carried directly from before backward in middle of the fossa from the tuber ischii and the outer margin of the anus. The nerve, the course of which is indicated by the pulsations of the accompanying artery, is carefully separated from this vessel and followed backward to its trunk. The main divisions supplying the muscles of the vulva and the painful area of integument are divided near their origins, and peripheral portions of the nerve twisted and torn away. In this operation care must be exercised to avoid the inferior hæmorrhoidal nerve and the anal twigs of the deep perineal branch.—*Revue de Chirurgie.*

Fracture of the Elbow-joint.—Scudder (Treatment of Fractures) says that fractures of the epicondyle, of the internal condyle, and T-fractures into the joint, are best treated by the "acutely-fixed position." Experimental evidence, both upon the cadaver and upon the anæsthetized living subject, confirmed by clinical experience extending over a number of years in hospital and private practice of many surgeons, demonstrates that the "acutely-fixed position" actively reduces and holds reduced the fractures previously named. In the "acutely-fixed position," the coronoid process in front, the troclear surface of the olecranon behind, and the fascia, posteriorly and laterally, together with the tendon of the triceps, posteriorly, hold the fragments reduced and close to the shaft of the humerus.

This method of treatment preserves the carrying angle of the arm. Other methods fail to do this.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 16, 1902:

	Cases.	Deaths.
Measles	87	4
Diphtheria and croup	134	20
Scarlet fever	65	6
Smallpox	2	1
Varicella	9	..
Tuberculosis	220	115
Typhoid fever	104	16
Cerebro-spinal meningitis	..	3

The Periodicity of Hemicrania in the Male.—D. Fraser Harris reports the case of a man who suffers from recurring headaches, but is otherwise in good health. The total number of his headaches per annum has been about the same for three years, an average of 31 a year. From the figures submitted the author concludes that it cannot be doubted that there is a rhythmic expression of the phases of altered metabolism. This hemicrania or migraine in the male might be defined as objectively, the periodically recurring climax or crisis of a phase of departure from the healthy normal of metabolism, and subjectively as the one-sided headache, usually with nausea, depression, and sleepiness. The author reports this case as a contribution to the discussion as to whether there is in the male anything corresponding to the rhythmic waxing and waning of metabolic intensity in the female as evidenced by the menstrual period.—*The Edinburgh Medical Journal.*

Infected Fingers.—H. A. Leipziger thus concludes his study of the subject. He would have no more lancing of infected fingers. The time when simple incision is indicated is so early that patients are seldom seen at that stage. He would always explain to the patient that sloughing or necrosis may follow the operation from the damage already done by the poison. A general anæsthetic is to be given, and the field of operation carefully and antiseptically prepared. The operation should be thorough and careful, as every portion of tissue is important to the function of the fingers. The doctors who lance these fingers get paid for lancing, and get, perhaps, all their services are worth; the surgeon who treats these cases correctly does skilful surgery, and deserves and should demand higher compensation than is usually considered applicable to this class of cases. The laity should be instructed in the truths of these propositions.—*The Railway Surgeon.*

Endemic Amœbic Dysentery. Jesse S. Myer desires to call the attention of those who may meet with this disease to santonin as a rational internal treatment. The employment of this medication in but two cases permits, of course, of no general deduction, but the results of the first case, which was a very virulent type of the disease, were so prompt and satisfactory that it seems justifiable to recommend its use. In the second case its results were not so prompt, but still quite apparent. Santonin is one of the few parasiticides whose action is maintained throughout the entire intestinal tract, and this would seem, therefore, a most rational mode of medication in the treatment of amœbic dysentery. The writer gives the remedy in three-grain doses in capsules with bicarbonate of sodium three times daily.—*St. Louis Medical Review.*

An Epidemic of Streptococcal Grippe.—Raymond Bernard and Denis de Casabianca describe an epidemic which occurred in the fifty-second regiment of infantry at Lyons in 1898, either by the contamination of the barracks or from isolated imported cases. In the hot months the disease was almost nil, but it came on in aggravated form in the winter, manifesting itself chiefly in attacks of erysipelas and infections of the respiratory passages. This periodical activity may, of course, be secondary to various epidemic diseases, the eruptive fevers especially, but that it may also be spontaneous and independent of all other infections, is what the authors endeavor to demonstrate. They wish to make a distinction between ordinary grippe or catarrhal influenza, and this special form characterized by the presence of the streptococcus.—*Archives Générales de Médecine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 16, 1902:

PLACENTA PRÆVIA WITH STATISTICS FROM THE LAST ELEVEN THOUSAND TWO HUNDRED DELIVERIES OF THE SLOANE MATERNITY HOSPITAL.*

By FRANKLIN A. DORMAN, A.M., M.D.,
NEW YORK.

RESIDENT PHYSICIAN OF THE SLOANE MATERNITY HOSPITAL; INSTRUCTOR IN OBSTETRICS IN COLUMBIA UNIVERSITY.

No complication in obstetrics may come upon one more suddenly and with more appalling results than this dreaded condition. Nothing in midwifery demands such combination of ready judgment and prompt action as the hemorrhage from a bad case of placenta prævia. We may think of eclampsia, its fearful manifestations, and its often fatal outcome, but to the trained man the warning signs are evident, and there is always time for deliberation and careful judgment. In placenta prævia we are sometimes faced, with profuse hemorrhage, which may be rapidly fatal. In fact, the doctor may find, on his arrival, acute anæmia already so far advanced that the results of interference will be grave.

Placenta prævia means a low placental insertion. The placenta may be entirely out of reach of the finger and yet be attached to the lower third of the uterus, or to what is known as the danger zone. The margin of the placenta may be above the internal os, reach to the edge of the internal os, partly overlap it, or may completely obliterate it. Normally, the placenta is attached near one or the other cornu or at the fundus. This complication is found so rarely as to suggest that some prominent etiological factors could be discovered in a large series of cases.

The frequency of placenta prævia varies with localities and in the same localities at different times. Jewett gives the average ratio as one in 1,000 cases; Hirst as one in 1,200. I present, with the kind permission of Dr. Edwin B. Cragin and Dr. James W. McLane, from whose services these statistics have been drawn, a series of eighty-four cases in 11,200 deliveries, or one in $133\frac{1}{3}$ cases. This ratio simply shows the high proportion of operative cases in an emergency obstetrical hospital, and is of no value for purposes of comparison with a general outside service.

Any condition which would interfere with the fixation of the ovum as it comes from the Fallopian tube, and which would permit the ovum to descend until it found a favorable nidus near the internal os, is an etiological factor. As such, we recognize relaxation and subinvolution of the uterus, and chronic endometritis. As predisposing to endometritis and uterine relaxation we have age and multiparity; chronic congestion from renal disease or endocarditis; injuries from operative deliveries, especially lacerations of the cervix; and new growths, such as fibroids or cancer. Winkel estimates that in cases of placenta prævia multiparity is to primiparity as four to one. In this series the ratio was eight to one. Fifty-two per cent were four gravida or over. Of the multiparæ 35 per cent. gave a history of difficult instrumental labors previously. One-half of the patients were over thirty years old. Eight were ten gravida or more. Seven were over forty years of age. Five cases suffered from albuminuria, three of them complicated with eclampsia. One case was complicated by fibroids.

Schwartz has called attention to the fact that the uterus bicornis may be a cause, and one of this series had such a condition. Ingleby found that a low insertion of the Fallopian tubes was a cause for repeated placenta prævia. He reports two cases, in one of which the condition had recurred in three successive cases, and in the other in ten successive labors. In one of this series placenta prævia recurred in two succeeding labors. In another case the patient gave a history of two previous abortions due to placenta prævia.

The first evidence noted of placenta prævia may be severe sudden hemorrhage, which is apt to occur independent of any other exertion. This is most alarming, because of the abruptness of its onset, its large amount, and persistence. Bleeding is more often apt to be slight at first, recurring from time to time, and rarely appearing until after the sixth month. Exceptions were found to this rule, in three cases, in which there was a history of bleeding as early as the second month, in five in which bleeding was noted as early as the fifth month. In five cases bleeding was first observed during the sixth month. Occasionally there is a continuous slight bleeding. In those cases in which the hemorrhage is severe from the start, the placental implantation is more apt to be complete, and the patient near term. In comparatively few cases does the patient go into labor with no signs of previous bleeding.

In the cases which I report, the bleeding at the onset was moderate and gradually increasing and independent of labor pains in 50 per cent.; in 10 per per cent. it began moderately after the beginning of labor; in 40 per cent. there was sudden profuse flooding; although in one-third of these cases slight preceding attacks of bleeding had given warning signs. The bleeding in the cases of complete placenta prævia, as has been already suggested, was more severe, and almost without exception came on suddenly. Over half of the women in this class went on to full term. Most appropriately has this type of hemorrhage been called "unavoidable." In very few cases was a history of over-exertion as an etilogical factor secured.

Two women bled suddenly while straining at stool; one on rising in the morning. Severe hemorrhage occurred first in two cases after a vaginal examination. Five presented themselves at the sixth month, nineteen at the seventh month, twenty at the eighth month, and forty at the ninth month.

The hemorrhage comes from the exposed ends of the uterine vessels at the place where the placenta has been torn away. Ordinarily, the contraction of the uterine fibers around the exposed blood vessels at the placental site prevents bleeding; but in the case of placenta prævia, uterine contraction is manifestly impossible. Unless there is some control of the hemorrhage by the descent of the fetal part or by an artificial tampon, the bleeding must continue until syncope appears or a firm clot forms.

---

*Read before the Society of the Alumni of the Post-Graduate Hospital.

The result of the condition is, therefore, without interference, rapidly fatal, except in those cases in which the placenta is fairly high, or in which the bleeding has not commenced until the cervix was well dilated. Cases of a favorable outcome even in central placenta prævia, by a spontaneous delivery with the placenta in advance, have been reported.

Part of the hemorrhage may come from the placenta from the maternal circulation, and possibly, if the placenta be extensively lacerated, from the fetal circulation. The bleeding of the patient in labor is apt to diminish during uterine contractions.

For *diagnosis* we must depend upon the history of the case and the results of vaginal examination. By abdominal palpation, it is very exceptional to be able to feel the placenta. Vaginally, if the placenta is between the fetal parts and the cervix, the difficulty in feeling the presenting part is noted. The fact that the head is riding high, or that there is a malposition, should arouse suspicion.

If the cervix admits the finger, the placenta, with its variously-described stringy, gritty, or boggy feeling, may be made out. Examination should be made with excessive care. I have seen, even in cases of a careful examination, severe and well-nigh fatal hemorrhage started up. Oftentimes a thickening and softening of the cervix, due to its increased blood supply, may be observed. I do not attach any importance to the detection of pulsation in the cervix or to a placental bruit heard over the lower uterine segment.

Finally, there are probably many cases of placenta prævia which do not overlap the os, which as they give no symptoms, are entirely overlooked and can only be diagnosed by the location of a marginal rupture in the bag of membranes.

As for the *prognosis*, the placenta prævia, clinically, *i.e.* with symptoms, must be acknowledged as a most dangerous complication. The maternal mortality is estimated by Churchill to be from 25 to 30 per cent.; by Müller as 23 per cent. Winkel believes that, with the best care, it should be from 5 to 10 per cent. Hirst says 10 per cent. Our own statistics show a mortality of 12 per cent.

Of the ten deaths four of the women were moribund on admission and died the same day shortly after delivery, from loss of blood and shock. In three others death was caused by a rupture of the lower uterine segment, and the shock, together with the hemorrhage, was the cause. One case was complicated with eclampsia. Two patients died of sepsis—one after rupture of the uterus.

The fetal mortality is very high. A certain number of abortions occur. About half of the children are premature. The separation of the placenta cuts off so much breathing space that asphyxia is the cause of death in the majority. There is undoubtedly in some of the cases bleeding from the fetal circulation. The complex, transverse, or breech presentations cause added danger to the child. The low placenta, often with a marginal or velamentous insertion of the cord and the malpresentations, predispose to prolapse of the cord. To these above dangers is added the necessity for an operative delivery by version, forceps, or breech extraction, in the interest of the mother. It is therefore not surprising that the statistics for the child are poor. Hirst estimates the infant mortality at 50 per cent., Müller at 64 per cent. Our statistics show 45 per cent. still-born and 12 per cent. dying within the obstetrical two weeks. If we except those cases in which the child was dead in utero on the admission of the patient, the mortality is 43 per cent.

The complications of placenta prævia are numerous. *Malpresentations* and *malpositions* are so frequent that one should be on the lookout for them. In eighty-four cases fifty-six were vertex, ten were breech, eighteen tranverse, and one face. The low placenta forcing the head away from the pelvic brim is always the cause of this complication.

Prolapse of the cord has been mentioned. It occurred in 26 per cent. of these cases. Anomalies in the shape of the placenta are common. As a result of a previous endometritis, the placenta is sometimes adherent. This condition existed in 13 per cent.

Postpartum hemorrhage is often seen, but prompt action should prevent much loss of blood in this way. The hemorrhage is usually from the uterine atony, due to the extreme anæmia, but is sometimes from the extensive cervical lacerations, and even from rupture of the lower uterine segment.

Sepsis is a very frequent sequence of placenta prævia. The patient's power of resistance is diminished by her anæmia. The placental wound is at the cervix and therefore relatively nearer infection. The poor contraction of the uterus and the slow involution in the puerperium predispose to sepsis. The operative delivery causes a greater liability to infection.

There was a temperature above 100.5° in 52 per cent. of the cases, but 15 per cent. of these had been examined and treated first by doctors outside the hospital. There were two deaths from sepsis. One case was complicated by phlebitis. Two cases showed hydramnios. Two were twin labors. The eclampsia cases have been mentioned. One case developed puerperal insanity.

The treatment must vary widely with different cases, as very different indications for treatment are presented. In those cases in which prompt interference is not, on account of active bleeding, imperative, labor should be induced and the patient constantly watched by the physician until the delivery is completed.

Expectant treatment is permissible only before the seventh month. If there is little loss of blood, one may wait until the time of complete viability of the child, *i. e.* until after the seventh month. Fatal cases before that period are practically unheard of.

The induction of labor may be by a tight vaginal tampon, or if the placenta is not completely covering the os, by the introduction of a bougie. Best of all is the introduction of the Champetier de Ribes' balloon; a very excellent American modification of which has been devised by Dr. James D. Voorhees of the visiting staff of this hospital. With it in the cervix we have a good uterine stimulant and a perfect tampon.

One rule must absolutely be observed, and that is not to leave the patient until she is delivered; and never to allow a patient with placenta prævia to go on in pregnancy beyond the seventh month, remembering that at any time hemorrhage so profuse may come on that the patient may die before the doctor can be secured.

If the cervix is partly dilated, a podalic or pelvic version may be performed by the external or bipolar method, and a foot secured and brought down until the half breech tightly fills the cervix. The external version in many of these cases ought to be possible, because of the mobility of the head above the pelvic brim. When the breech has been brought to present, then, by a quick rupture of the membranes or boring through the placenta, the foot can be secured and brought down with a minimum loss of blood. The external version should more often be employed in cases of this sort.

If the cervix is fairly dilated or dilatable, the hand should be carried into the uterus and the fœtus turned by podalic version. The completion of the dilatation is then left to the uterine pains, or, in the interest of the mother or child, may be effected by breech extraction by intermittent tractions on the leg.

The chief consideration in our treatment of these cases is control or prevention of the hemorrhage; which is accomplished by the methods above enumerated. The second consideration in advanced cases is the combating of shock. This condition may be so marked that for a time we must delay delivery until the patient is in better shape.

The regular treatment for hemorrhage and shock is employed, but most energetically. The intravenous infusion is invaluable. I have seen it save many lives on the obstetrical table.

Should the placenta be partial or marginal, we may sometimes, if there be fair cervical dilatation, succeed in stopping the flow by rupturing the membranes and thus permit the head to descend and exert pressure. The use of forceps in such cases as th[illegible] justifiable.

The statistics which I have gathered show, in eighty-four cases, induction of labor performed thirty-one times; accouchement force, thirty times; dilatation of the cervix, thirty times; tampon of vagina, three times; internal podalic version, fifty-three times; Braxton Hicks' version, eight times; partial podalic version, three times, and external version, two times (a total of sixty-six versions); the low forceps were employed once, medium four times, and the high, once. Breech extraction was employed in sixty cases.

The prevention of postpartum hemorrhage is possible by use of the hot intrauterine douche, which should always be in readiness; or prompt tamponade if the uterus does not quickly react to the douche. After delivery it is sometimes necessary to employ vigorous methods to combat shock—free stimulation, heat externally, elevation of the foot of the table or bed, saline enemata, hypodermoclysis, or the saline intravenous infusion.

The treatment of the subsequent anæmia is important. Saline enemata of a pint each may be given every two hours until the fluid bulk of the blood is restored. Small doses of morphine may be needed for the extreme restlessness. As soon as the stomach will tolerate it, fluid diet should be given, and a liberal nourishing diet in a short time. Some easily digestible form of iron should be exhibited early.

From our statistics the following conclusions may be formed: firstly, that uterine relaxation and endometritis as important etiological factors are well shown; secondly, that the immense variation in the types of bleeding should warn us to look upon every bleeding at any time in pregnancy with suspicion; thirdly, that the very great possibility of sepsis should cause us to employ every precaution in asepsis. The necessity for exceptional care during the breech extraction, where the cervix is not completely dilated, is apparent. The cervix in this condition is unusually vascular and soft, and tears with fatal readiness.

The chances are so great against the child that any eagerness to save it should not lead us [illegible] risk to the mother's life. The four cases of uterine rupture were accomplished in this way, and by men who were experts in their work and knew the danger which they were facing.

In connection with postpartum hemorrhage, a danger may exist from too great dilution of the blood by intravenous infusion. The blood loses its power of clotting and the watery fluid will ooze through the tightest tampon. Moderation, therefore, should be used in the amount of the infusion. Repeated infusions of smaller amounts are preferable to one or two large ones of one to two liters each.

As some operators now show a mortality of practically nil in the Cæsarian section, the question arises whether there might not be some application of this operation in the placenta prævia. In those rare cases in which the placenta is central or nearly so, the cervix rigid and undilated, the patient in good condition, and everything in the surroundings is favorable for a laparotomy, I believe the operation would be justifiable. This combination of conditions is very exceptionally found.

These records show in their perusal, as mere reading of statistics cannot, a very inspiring series of struggles of the physician for the lives of patients; of numerous cases in which the woman has been saved by the greatest effort from what seemed, at the time, quickly impending death. From these we may learn that the fight must never be given up while the spark of life remains.

THE OPINIONS OF DIFFERENT SURGEONS AND PATHOLOGISTS AS TO THE ORIGIN AND CAUSE OF FIBROID TUMORS.

By MARY A. DIXON JONES, M.D., F.R.M.S.,
NEW YORK.

After giving the results of my own observations as to the origin and mode of formation of myofibroma, I was interested to know what the many eminent surgeons and standard authors may have said on the subject. So far as I had seen, there were apparently no positive views. Many admitted that their theories were mere suppositions.

Henry T. Green of Charing Cross Hospital says:[1] "Of the etiology of tumors as a class, nothing certain is known."

Ziegler, professor of pathology in the University of Freiburg, says:[2] "The etiology of tumors is not uniform, and often cannot be determined with certainty."

William M. L. Coplin, professor of Jefferson College:[3] "The causes of tumors are largely theoretic."

Alfred Stengel, professor in the University of Pennsylvania:[4] "The causes of fibroma are as obscure as those of tumors in general."

Dr. E. E. Montgomery, professor of Gynecology in Jefferson College:[5] "The causes of fibroid tumors are unknown."

Henry D. Ingraham, professor in the University of Buffalo, says:[6] "The cause seems to be as unsettled as at any previous time. As to the exciting cause, nothing whatever is known."

Cohnheim, professor of general pathology in the University of Leipsic:[7] "There is no chapter in our science so deeply involved in obscurity as is the etiology of tumors. Hypotheses, indeed, abound, and on consulting the textbooks you will find an ample list of tumor formations. But of what value are they?"

Pozzi, professeur à la Faculté de Médicine, Paris, says:[8] "In spite of the patient researches which have been made on this subject, we still know nothing positive about the exciting causes of uterine fibroma. We can only give certain predisposing conditions, among which are race (the negro being more subject to such tumors than the white) and advanced age; in the white races the most susceptible age is from thirty to forty. Sterility is not so much a cause as a consequence."

Probably we would find that the same cause that produced the sterility caused the growth of the tumors. Cohnheim asserts that the factors usually given, such as age, sex, social position, etc.—a direct casual relationship between them and the new formation—cannot by any possibility exist.

Pozzi himself declares: "All the local existing causes which have been advanced are without proof. On the other hand, it has been supposed that a celibate life disposed to their formation, but Gusserow's statistics disprove the idea. Fehling has attributed great importance to incomplete involution after labor and abortion. Prochownic thinks that the specific irritations due to syphilis, malaria, and typhoidal infections may have a pathogenic action in the devélopment of fibroids."

Pozzi further says: "Klebs asserts that these fibrous tumors have their origin in a proliferation of the connective tissue and the muscular layers of certain vessels; the different nodules thus formed become agglutinated to make one tumor. Klimwachter describes the evolution of fibromata as due to a round cell, which is found along the capillaries and produces a partial obliteration of them; these cells then become fusiform and produce the nodules. Gettschalk thinks that all fibromata originate by an endarterial proliferation, rapidly followed by an increase of the cellular elements surrounding the artery. Local irritation and circulatory disturbances would be the principal agents in this pathological process."

Pozzi declares, "Our knowledge of this subject is very limited." Adding: "These neoplasms are very frequent; according to Bayle, who describes certain anatomical features of them in 1813, a fifth of all women over thirty-five years old have fibromata."

We turn to the excellent work of Professor Senn.[9] He says, on page one: "When we realize the amount of suffering and the number of deaths resulting from tumors, it appears somewhat strange that this vast department of pathology has received so little attention on the part of modern investigators. Recently a good deal of work has been done to establish the microbic origin of malignant tumors, but no positive results have been obtained so far, and we must confess that but little additional light has been shed on the etiology and pathology of tumors since Virchow and Cohnheim."

Professor Senn further remarks: "Chronic inflammation was regarded for a long time as the essential etiological factor. These and many other vague theories advanced in regard to the origin and nature of tumors, prior to the time they were recognized as a part of the body they inhabited, the result of proliferation of pre-existing cells, do not merit an extended discussion in a modern textbook."

Fibroid tumors do not originate from chronic inflammation, nor are they the proliferation of preexisting cells. *Pre-existing cells cannot create and make tumors.*

Dr. Senn says: "Cohnheim imparted a new stimulus to the study of tumors, advancing a novel theory in reference to their origin. It appears recently that Durante of Rome was the real originator of the theory of embryonic origin of tumors, as his publication on the subject antidates that of Cohnheim by one year."

Dr. Senn tells us "Cohnheim referred every tumor to its proper embryonic layer, and claimed that a tumor never had its origin from mature tissue, but always developed from the matrix of embryonic tissue. This essential tumor-matrix he traced back to its embryological source. He believed that during the process of cell differentiation in the embryo, groups of cells not utilized in the growth of the embryo, or displaced, were arrested in their further development, and remained in a latent condition until the activity was awakened later, when the product of their proliferation resulted in the formation of a tumor."

We certainly admit that tumors are developed from embryonic material; but that there are "groups of cells not utilized" and that they are "arrested in their further development"—would not this indicate some defect in our organization; and "that the product of their proliferation should result in the formation of a tumor?"—would not this argue some most serious mismanagement?

The human body was made in perfect wisdom. There were no defects, no arrested development, no tissues remaining in a latent condition, certainly no arrangement beforehand for the formation of abnormal growths or fibroid tumors. All tumor formations come from some changing pathological state, and can only be formed by the tissues being diseased and thereby reduced to a medullary condition.

Professor Senn says that "Cohnheim's theory found many supporters, but at the present time only a few authors uphold it in its entirety. As we shall see farther on, it has much to recommend it, but it does not satisfactorily explain the origin of all tumors." Yet Dr. Senn declares: "In the absence of better proof of the origin of tumors, the writer will adhere to the doctrine advanced by Cohnheim, and in addition to it will claim that *the essential tumor-matrix may be composed of embryonic cells, the offspring of mature cells, which for some reason have failed to undergo transformation into tissue of a higher type, and which may remain in a latent, immature state for an indefinite period of time, to become,* under the influence of either hereditary or acquired existing causes, the essential starting point of a tumor."

So this great surgeon and pathologist, in a measure, adopts these uncertain and contradictory views. That there are embryonic cells, that remain in a latent immature state, and then become the essential starting point of a tumor.

If this principle is true, who can tell what special embryonic cells may fail to undergo transformation into tissue of a higher type? For instance, the group of cells that are to form the eye, the ear, or any other organ, why may not these fail, remain in a latent, immature state for an indefinite period to become themselves the essential starting point of a tumor? And thus, in this sad uncertainty we might have a tumor instead of an eye or an ear or some other organ. Have we any security that any group of cells may not fail to undergo transformation into tissue of a higher grade, and remain in a latent, immature state till they become the essential starting-point in the formation of a tumor, which is thus formed, instead of the normal structure. If such principles rule, what may we not expect, and where will be the end of chance and change?

Again, if fibroid tumors are the offspring of "mature cells," why may we not call them normal structures? This certainly must be the conclusion. But again comes the question, how can mature cells—

we understand what they are—unless they are rminal material or protoplasm, produce other owths? One tissue cannot produce another. Then ere are in the human system "mature cells that il to undergo transformation into tissues of a gher type?" This would surely indicate some fect in our organization? How can we suppose at any structure or group of cells fails to undergo rmal transformation, and that it remains in a tent, immature state for an indefinite period and en becomes the essential starting-point of a tumor?

Professor Senn well says (page 19): "So long as ir ideas in reference to the origin and nature of mors rest exclusively on a theoretical basis, it is ident that no satisfactory definition can be given. he definition of each author must necessarily vary cording to his views on the subject. A few definitions will be given to corroborate the correctness this statement. John Hunter thus defines a mor: 'A tumor is a circumscribed substance pro- iced by disease, and different in its nature and nsistence from the surrounding parts.' Bär re- rds the characteristic feature of a tumor as 'an tive multiplication of cells, which takes place dependently of inflammatory processes.' The ocess which leads to the formation he 'calls a mon- rosity in the development of cells.' Lücke: 'An crease of volume by the production of new tissue, ithout a corresponding physiologic function.' rom these definitions, says Professor Senn, it be- mes apparent how difficult it is to give even an proximately correct definition of tumor."

Among the definitions quoted above by Professor nn, that of Dr. John Hunter is the most correct d the nearest to truth, reason, and the highest achings of physiological principles. Bär's definion would strike one as an impossibility. Dr. Senn ys (page 720): "One of the greatest difficulties in e way of a proper appreciation of what is meant by tumor is a failure on the part of authors and achers to draw a dividing line between tumors and lammatory swellings."

On page 20 Dr. Senn declares: "*A tumor is a calized increase of tissue, the product of tissue- oliferation of embryonic cells of congenital or p st- ital origin, produced independently of microbic uses.*"

On page 656 the author says: "All true tumors e composed of new tissue produced from matrices embryonic cells. All inflammatory swellings are mposed of or are derived from pre-existing tissue." n page 26 he emphasizes, "*We regard the matrix of nbryonic cells as the essential cause of tumor forma- n, without which all intrinsic or external exciting uses are inadequate to produce a tumor.*" On page 4. "A myoma is a tumor composed of muscle ssue produced from a matrix of myoblasts."

I hold that both tumors and inflammatory swell- gs are derived from pre-existing tissues; and I have own that a fibroid tumor of the uterus, or a myo- broma, is a new growth, resulting from the tissues the uterus being, by some infection or microbic use, reduced to inflammatory or medullary tissue.

Cohnheim,[10] in his work "Lectures on General athology, 1889," seems to consider it necessary, as ustrative or explanatory of his principles, to give rst: "*Laws regulating the growth of the genitals, and particular of the gravid uterus;*" "*Monatra par cessum.*" He then gives "*Etiology of Tumors;*" *Refutation of the traumatic and infective theories of usation,*" "*Relation of the congenital rudiment to e development and growth of the tumors, etc.*"

This distinguished author startles us with many nexpected theories. He says, page 747: "For only consequence of organization—that is, of the original disposition of the germ—does the growth of the genitals during childhood simply keep pace with or even lag behind that of the remainder of the body, and then suddenly become greatly accelerated and increased. Here," says he, "you have a growth determined by the disposition of the germ, and yet one which is beyond doubt *abnormal*, and only escapes being pathological for the reason that the growth of the child is, according to the type of our organization, normal but for a definite period."

Are we justified on technical or scientific grounds, in pronouncing any function of the body or the time of its appearance abnormal? Infinite Wisdom has made the human body and there are no imperfections. To each organ is given certain times and periods for action. A specified time the brain can act, so of sight, hearing, digestion, or any function. They must all have their periods of rest. These functions have been going on for centuries, and always by fixed rules, and without the least flaw, except from pathological conditions.

Cohnheim continues: "But the history of the genitals offers a still more striking example of abnormal growth, depending on inherent disposition in the *enlargement of the uterus during pregnancy.*"

This also abnormal? This most important and frequent function of one-half of the human race? If abnormal, would there not be continued departures, irregularities, and unexpected variations, and even, at times, grotesque presentations? Instead of that, there is not a departure from the exact standard except from acquired disease, or some recognized pathological condition. It is always the same, the same remarkable powers of development, the same functions, and the times of their performance. Six thousand years ago, we are told, "Her days to be delivered were fulfilled."[11] This was a fixed period, and in all the nations of the earth it is the same to this day. No uncertainties or irregularities.

The author says: "The pregnant uterus, whose office is anything rather than contraction, nevertheless acquires, in a comparatively short time, dimensions many times greater than the original."

The uterus is a powerful muscular organization, and in every respect this organ shows a wonderful adaptability to its offices of contraction. It is equally adapted to its other functions, which are equally normal, namely, of carrying, nourishing, and supporting for nine months the young fœtus, the growing human being. How, we do not know; but we do know that these functions are not pathological.

Cohnheim gives us to understand that this abnormality as to the enlargement of the uterus depends on "the original disposition of the germ, which is, at any rate, exceptional, and which we term normal merely because it is established in the type of our organization."

Who fixes the standard of what is normal, and decides the abnormality? Pregnancy is one of the functions of the human body, and long years ago its conditions and processes were arranged and established by Infinite Wisdom, and there is nothing abnormal, nor are there any defects. No one organ in the body is more frequently mentioned in sacred writ than is the womb, and not once is there an intimation of any abnormality or any uncertainty in its processes. Nor do I believe we can find any abnormality in its structure or functions except from disease. We do not begin to understand all its processes, or physiological changes, or powers, or functions. In the sacred volume we read: "Thou art He who took me out of the womb."[12] So Infinite Wisdom has fixed the plans and established the processes. "Thou knowest not how the bones do grow in the womb of her that is with child. Even so, thou knowest not the works of God who maketh all."[13] All is beyond our comprehension. Yet here comes one in the latter part of the nineteenth century of the Christian era and tells us that all these wonderful arrangements are abnormal!

On page 752 the author says: "I have not now in mind the clinical significance of the word tumor, which, as you know, is applied to every possible increase of volume recognizable by the sight or touch. In this sense the gravid uterus is a tumor." Cohnheim also asserts (page 749): "By morbid embryology the entire class of *monstra par excessum* is explained by supposing abnormality of the embryonic germinal material."

Have we any right to suppose "abnormality" of the germinal material? The author adds: "That these are really examples of abnormal growth depending on the original disposition of the germ, will at any rate not be disputed."

Who can prove that abnormal growths depend upon "the original disposition of the germ"? If so, we are to understand that these germs were arranged from the beginning to produce abnormal growths? A sad, sad conclusion. I doubt the whole theory. I do not believe there is any irregularity, or anything abnormal, in the germinal material. Cohnheim himself says, on page 749: "We know too little of the details of growth of the different tissues to enable us to state in what consists the abnormality of the germinal matter in these cases." Yet this author says (page 750): "I think you will not doubt for a moment that the abnormal growth is here caused solely by irregularity in the germinal material." The author adds: "Nor can I imagine any more plausible explanation for all the forms of duplicity."

Should scientists present what they "imagine" as proof of a theory, or as an illustration, or even as a "plausible explanation?"

Cohnheim assures us on page 750: "There is nothing mystical in the view that the disposition of the germ is one of the causes of excessive growth; that it is so both of the physiological growth of the genitals at puberty and of the uterus during pregnancy, as well as in the pathological development of the *monstra par excessum*, and it must be made to embrace a much more extensive and therefore important domain, that of true *tumors*."

So tumors not only come from the original disposition of the germ, but, from the beginning, arrangements were made for these growths!

I would say that the whole of the "extensive and important domain of true tumors," and all "irregularities," as *monstra par excessum*, etc., *come solely from pathological conditions in the individual, or in his or her ancestors.*

In regard to tumors, Cohnheim says: "We here enter a field which from the earliest times has been the arena of multifarious speculations," and he even declares, on page 752, that "to attempt a general description of a tumor would be a foolish undertaking"; and that, "among the supposed or direct causes, none play a more important rôle than the so-called local irritants or traumata." "But," says Cohnheim, "How little support the assumption of such a connection receives. Investigation directed expressly to this point failed in almost 86 per cent. to establish the previous occurrence of any kind of trauma"; adding, "how extremely frequent are contusions and other injuries of the shin-bone, and how very rare the special tumor formation. How fearfully common would mammary tumors be if it were true that traumata led easily to tumor formation."

That traumata cause the formation of tumors is Virchow's theory, but Cohnheim asserts that "we know of cogent reasons for rejecting the notion of casual connection between injury and true tumor;" and that, "in support of the statement that any kind of cells increase or commence to proliferate as a direct result of an external traumatic impulse, there exists no shadow of truth, so far at least as the normal human organism is concerned;" and "he would infer therefrom that an inflammation which usually leads simply to the formation of connective tissue may suddenly, on some occasion, result in the production of muscle fibers, etc., deprives himself at starting of every chance of understanding the inner relationship of pathological processes."

The learned author here admits that "inflammation leads to the formation of connective tissue." This is a great fact, and everywhere acknowledged. *In the same way, and on the same principle, from inflammation, muscle fibers may be evolved.* Thus we have the formation myofibroma of the uterus, as the result of inflammation or disease of the organ.[13] There is first infection, then inflammation, which reduces the tissues to a medullary condition, and from this medullary tissue is formed the myofibroma. This is the principle; this is nature's law In the same manner, when tissues are reduced to inflammatory or a medullary condition, carcinoma may be developed. This I proved in 1892, and again stated the fact in a short address before the New York State Medical Society in Albany, January, 1901.[14]

From medullary tissue may grow or be developed any abnormal growth. No one can set bounds as to the action of life elements; but all these secondary formations are pathological structures.

The above facts that I have mentioned give us a clear explanation of the origin of fibromyoma and of other abnormal growths.

Cohnheim's theory involves us in many mysteries Cohnheim declares: "The simplest view appears to me undoubtedly to be, that in the early stage o embryonic development more cells are produced than are required for the building up of the part concerned, so that there remains unappropriated a quantity of cells, which, owing to their embryonic character, are endowed with marked capacity for proliferation." Then he says: "The only point on which I lay any stress is that the real cause of the subsequent tumor is to be sought in a fault or irregularity of the embryonic rudiment." Adding (page 760): "If you ask me wherein the abnormality of the disposition of the embryo that becomes the starting-point and cause of a tumor consists, I can only answer with hypothesis; convincing positive evidence cannot, in the nature of the case, be produced." So there is no positive or certain evidence! Cohnheim says: "We assume, in accordance with the view formulated by us, the existence of the excessive cells, out of which excess a tumo ultimately develops."

Is it proof of a point to say, "We assume, in accordance *with the view formulated by us?*" Can that be considered a proof of a statement? The author says, further (page 764): "The new-born infant brings with it into the world, not the tumor, but the superabundant cell material out of which if circumstances be favorable a tumor may grow later on."

Then, the arrangements for these tumors are no only made before birth, but the material is born with us! Hence it follows that these pathologica formations are not the results of disease, but are Divine institutions.

Cohnheim tells us (page 768) "that the existence of these predisposed localities has been regarded by Virchow and others as strong proof that mechanical irritation is of essential importance for the etiology of tumors. Yet, on reflecting, how rarely tumors—and especially cancerous tumors—are met with on the *hands* and *feet*, the parts which more commonly suffer violence, one finds it difficult to accept such a connection."

He continues (page 769): "Everyone knows that a great majority of smooth myomas have their seat in the uterus. Why," said he, "should a form of tumor rare elsewhere develop with such extreme frequency precisely in the uterus?" His reason is, as given on page 770: "The germinal material is present in every uterus, and only awaits a physiological stimulus to actually grow."

As I see it, fibroid growths are diseased structures, and result from diseased conditions; and they are the cause of great suffering, of much ill health, and frequently of death. But from the above theories we are rather given to understand that they are *Divine gifts*—that the Infinitely Wise One, at the great Creation, after saying, "Let there be lights in the firmaments of the heaven," may have added, "and let there be placed in the womb of women germinal material to develop into tumors; and then all things can be pronounced very good."

The author speaks of these tumors being incapable of doing any work, and of their immense detrimental effects; yet we are given to understand that before birth arrangements were made for their existence—for the existence of these abnormal growths, and diseased structures!

I assert that the reason why the uterus is so frequently the seat of these growths or tumors is not because any germinal material may be there, but because the uterus, most unfortunately, is the frequent seat of infection; and why the tumor that is developed is most frequently a myofibroma is because the wall of the uterus, from which the tumor is evolved, is composed of muscle fibers and connective tissue; and the reason why these tumors do not develop until after puberty is because septic conditions are not so apt to occur till that period.

When we see how frequently sepsis is produced from various causes we may conclude that the number of fibroid growths will go on increasing—growths capable of producing the most fearful consequences—and may produce the most intense suffering. Fibroid tumors are the results of disease; they are always accompanied by inflammation, which inflammation results from some infection, which infection more or less pervades and affects the whole organ. This proves that *fibroid tumors, like every other disease or ailment, result directly or indirectly from violations of the laws of health.*

Cohnheim, on page 761, admits that, "owing to our imperfect knowledge of the details of the process of growth, we are unfortunately still compelled to have recourse to guesses;" adding, "I put no value on the formulation itself, but am ready at any moment to exchange for a better."

Probably, if this great and learned scholar were now here, he would be willing to exchange his complex and impossible theories for the clear and simple ones of truth which appeal at once to reason, and which are according to Nature's recognized processes and the great laws of our being. He would, too, see the beauty and simplicity of the theory, and would recognize the inextricable difficulties and contradictions connected with his impossible suppositions.

This great pathologist was many times trembling on the verge of light. The germs of truth pressed forward, but somehow he pushed them back. For instance, he says, on page 766: "It is possible that the constant wearing of heavy earrings by an individual predisposed to cutaneous fibroma may lead to the appearance of true fibromas in the lobe of the ear." If he had only looked a little more he might have seen the explanation—that the earrings may produce some irritation or break in the fine tissues, infection gets in, and inflammation results; and from the primal elements come the fibroid growths.

Professors Delafield and Prudden, in their excellent work, "*Handbook of Pathological Anatomy and Histology*, 1901," on page 262, say: "The reason why we cannot more accurately characterize tumors in distinction from other new tissue formations, is chiefly because we do not yet know what are their immediate excitants." On page 263, "Tumors are composed of the same types of tissue as those normally existing in the body, and from the latter they are derived by a proliferation of pre-existing cells." On page 267 the authors say: "The etiology of tumors is one of the most complex and in many ways difficult subjects in general pathology;" adding "it is rather a matter of surprise that ever-changing, self-regenerating, living tissue does not oftener go astray in its activities than that it should only now and then do so."

"In regard to the causation of tumors," the authors say, in the edition of 1898," our actual knowledge is still very meagre. In a certain number of cases mechanical influences are undoubtedly sufficient inciting causes. In other instances heredity is an important factor. But to both of these influences too much importance has been attributed in former times."

On page 269, last edition, they say: "Cohnheim has framed an hypothesis to the effect that all true tumors are due to faulty embryonic development. In accordance with this hypothesis, cells which in the course of development of the body may be displaced or become superfluous, or do not undergo the usual changes, may remain for long periods unaltered, but liable in later life, from whatever reason, to commence growing with all the potencies of lowly-organized cells in the midst of the mature tissues. . . . Cohnheim's hypothesis still lacks a morphological basis, since no one has seen the postulated, strayed, or dormant embryonic cells. This hypothesis is not, in any event, of universal application. . . . While the hypothesis of the embryonal origin of tumors is quite fascinating, and for certain forms quite satisfactory, we may well demand a more definite basis of fact before accepting it as of universal application."

Henry T. Green (Charing Cross Hospital), in his book, "*Pathology and Morbid Anatomy*"[15] says: "It is impossible to give an accurate definition of the meaning of a tumor, because its real nature is not understood. It is generally described as a formation of new tissue which is abnormal to the part, which performs no physiological function, which tends to continuous growth, and is more or less independent of the general nutrition of the body, and which has not arisen from the causes or in the course of inflammation."

"That tumors are formations of new tissue, necessitates the rejection of all swellings due solely to retention of secretions (retention cysts), or to extravasation of blood (hæmatomata)."

The author makes the assertion (page 192): "*A tumor is an atypical new formation, not the result of inflammation.*" "The histological processes which give rise to the formation are doubtful in the extreme. It is uncertain whether a tumor grows from a portion of the mature tissues or from a kind of 'resting-spore' of embryonic tissue, as suggested by Cohnheim."

On page 204, edition of 1898, Professor Green says: "Against Cohnheim's view it may be said that nothing is really known of such embryonic remains."

In the edition of 1900, page 88, Green says: "Several objections may be raised to Cohnheim's theory. The 'rests' or isolated cell growths, upon which it is based, are not actually found with any frequency within the body. . . . No transition stages are found between the masses of cells and actual tumors."

Professor Green says of the "theory of chronic irritation," page 89, edition of 1900): "The frequency with which instances of chronic irritation occur, and the relative rarity of the appearance of tumors in connection with them, render it certain that irritation alone is not sufficient to cause tumor formation."

Of the "etiology of tumors" (page 201, edition 1898), Professor Green declares "little is really known on this point;" adding, "in our present state of ignorance, no satisfactory classification of tumors is possible."

Professr Ziegler of the University of Freiburg gives, in his work, "*General Pathology*, 1899" (page 298), the following definition: "A neoplasm or spontaneous new growth—or tumor, in the narrower sense—is a new formation of tissue, not produced by infection, which has an atypical structure, serves no useful purpose in the organism, and to whose growth there is no definite characteristic termination." He says: "Tumors arise from a proliferation of the fixed cells of the part, and with the process is associated the formation of new blood vessels."

Can the fixed cells of any portion of the body proliferate any structure or form new blood vessels? As I read Nature's book, there is only one way, by the special-tissue being reduced to medullary or embryonal material.

Professor Ziegler further states (page 301): "The exact determination of what should be included under the term of tumor is scarcely a possible thing, and consequently the word is used by different authors differently;" adding, "that the etiology of tumors is by no means uniform, and often cannot be determined with certainty. That the etiology of tumors is not always the same, is shown by the variety of conditions under which they arise. It is hard to say what is the nature of the influence which causes the cells to produce an *atypical* form of tissue."

Of Cohnheim's theory Prof. Ziegler says: "This view receives no support either from the results of clinical observation or from those of anatomical investigation of the tissues."

Walter S. Lazarus-Barlow, demonstrator of pathology in the University of Cambridge, says: in his "Manual of General Pathology, 1898": "Though it is impossible to frame a definition of the new growths which shall be above criticism, a definition of some kind is convenient. We shall adopt that of Ziegler.

The author then presents, on page 555, six distinct hypothesis to explain the pathogenesis of new growths:

First. The theory of spermatic influence. By this theory it was assumed that the normal tissue of the part in which a growth occurs has become directly converted into the tissue of the tumor.

Second. The theory of traumatic causation. To this Virchow gives the greatest measure of his support.

Third. The theory of embryonic remnants (Cohnheim).

Fourth. The parasitic of infective theory.

Fifth. The theory of anaplasia (Hansemann).

Sixth. The theory of growth-liberation (Ribbert).

The author says of Cohnheim's theory: "There is no more fascinating chapter in Cohnheim's 'Lectures on General Pathology' than that in which he unfolds his doctrine of embryonic remnants for the explanation of new growths."

Alfred Stengel, University of Pennsylvania ("A Text-book of Pathology, 1899"), says: "Cohnheim's theory is not by any means universally applicable."

Cornil and Ranvier, in their "Manual of Pathological Histology, 1880," page 697, say: "Lesions of the uterine wall mostly consist in a new formation of smooth muscular and fibrous tissue, which occasions either a general or a local hypertrophy of the wall. A local hypertrophy, when sharply limited, may be regarded as a myoma."

The authors state that West regards the formation of myomata as a result of activity of the uterus while the organ is deprived of its physiological function, which is gestation—for example, when married women do not have children. "Yet," say the authors Cornil and Ranvier, "local and general hyperæmia of the uterus are also seen in women who do not have children."

Dr. B. W. R. Williams ("Uterine Tumors, Their Pathology and Treatment, 1901") says (page 49): "The outcome of recent researches as to the genesis of these tumors indicates that in a large proportion of cases they are intimately associated with developmental irregularities; and conditions of this kind are probably the chief morphological factors in their development. The author further states: "When Cohnheim first announced his theory of the origin of tumors from sequestrated fragments of the generating tissues, very few facts could be adduced in support of it. No one then believed in the possibility of such an amount of developmental irregularity as it presupposed. The light of modern science has, however, effectually dissipated this misconception, and our eyes have been opened to the hidden defects of normality. Sequestrated fragments of the various tissues and organs have now been found to exist in every part of the body that has been especially examined for them."

This last paragraph the author not only gives in his book, but presents in the *British Gynæcological Journal* (May, 1901, page 50): Still we are not quite ready to admit that there are "developmental irregularities" in the system, or that there are "hidden defects of normality." He repeats that "the origin of these tumors is more closely associated with embryology than with bacteriology;" adding, "if the foregoing views as to the origin of myomata be correct, it follows that local irritation and chronic inflammation play but a secondary part in their causation; and the altered condition of the endometrium that accompanies uterine myomata is a consequence rather than a cause of disease."

From what I have studied, I cannot see but it is disease of the endometrium, and of other tissues of the wall of the uterus, that causes the formation of the tumor.

Dr. Williams calls attention, on page 51, to the frequency with which "myoma are complicated with ovarian cystomata." It is the same infection that causes disease of the ovaries and the tubes, that causes the formation of fibroid tumors. So far as I have examined, *in every case where there was a fibroma of the uterus, the tubes and the ovaries were found to be diseased.*

The author still further emphasizes this idea by quoting, on page 52, the names of several surgeons who have found "multiple uterine myoma associated with cystic disease of the ovary;" and saying, on page 104, under "Complications of Myoma:" "The ovaries are always more or less diseased. They are congested and enlarged, the blood vessels are thickened, and small cysts are frequent."

This is all very true; but, so far as I know, I was the first one who called attention to this important fact. I said in the *New York Medical Journal*, August 25, 1888, page 202: "There must be some connection in the way of cause and effect, between diseases of the uterine appendages and a fibroid tumor or a uterine myoma; and that when there was a fibroid tumor of the uterus, the tubes and ovaries were always found diseased."

In the same article I made a yet more important announcement. "In removing the uterine appendages or diseased conditions I have frequently been surprised to find in every instance the uterus enlarged more or less, either from hyperplasia, or an incipient fibroid growth, more likely the latter condition—they are similar in nature—and the removal of the diseased appendages not only prevented the evil which their diseased condition would do to health, constitution and general system, but also the injury they would do to the uterus itself, in changing its structure or developing fibroid growths."

The last paragraph I had scarcely noticed or read since the article was published, but now, since studying the subject for a dozen years, I marvel at the clear intuitions therein contained. It was almost an inspiration. It really gives an intimation of the origin of fibroid tumors. I could not then see it.

But before this I had said, in the MEDICAL RECORD, August 25, 1886, when removing the uterine appendages for fibroma of the uterus, "It seems almost a question whether we were operating for cystic ovaries or for a fibroma."

As to diseased blood vessels, which Dr. Williams also emphasizes, if he will look in the *American Journal of Obstetrics*, February, 1888, pages 164–6–7, he will see where I speak of diseased blood vessels. So far as I know, I was the first one who called attention to the various diseased states of the blood vessels in diseased ovaries. I repeatedly spoke of "endarteritis obliterans," and how the closed blood vessels were often reduced to waxy and colloid masses.

Dr. Williams, as if sustaining his first theory, further remarks: "The frequency with which uterine myomata are multiple might of itself lead us to suspect the association of developmental irregularity with the origin of these tumors."

When disease is extensive there may be a number of tumors produced. When there is one tumor in the uterus we shall invariably find the beginning formation of others. As in the case I mentioned in "Annals of Gynæcology," April, 1901, when the uterus was first removed it weighed not quite one pound (15 oz. 5 drams), and from the outside were projecting eight growing fibroids. When subsequently, in further studying this uterus, I made sections of the same, I found in the stroma or in the walls a number of groups of growing fibroids. (MEDICAL RECORD, September 14, 1901, page 402.)

Whatever may be the seeming difficulties, or however varying the different views presented, I believe there can be a clear exposition of the causes and the origin of fibroid tumors without resorting to Cohnheim's theory.

On some points Dr. Williams seems to go further than Cohnheim. He says: "Lacerations of the cervix are of embryological origin," and that there are indications or intimations of defect in the first formation.

In the best developed uterus there may be a laceration of the cervix. The cause of lacerations is that the cervix is the seat of an inflammation, and after inflammation the muscle tissue changes to fibrous connective tissue, and during parturition fibrous connective tissue cannot dilate or expand, as muscle fibers do, so there is a rupture, "a laceration of the cervix."

Dr. Williams says, page 126: "I think there can be no doubt that the suppression of maternity and diminution of natural fertility are among the most important factors in the genesis of these tumors."

The same sepsis that causes the growth of the tumors destroys more or less and in time will destroy the entire capability of conception.

Dr. Williams says: "Myomata increase in size just before and during menstruation, and decrease afterward."

How can menstruation change the size of these solid tumors?

Dr. Williams further states: "There are good reasons for believing that the liability to myomata increases with advancing years."

Myomata develops only when there is disease, no matter what the age may be.

Page 123: "The menstrual history of myomatous patients shows that, prior to the onset of the disease, they have almost invariably enjoyed excellent health in this respect, being, in fact, far freer from irregularity and pain and other catamenial derangements than the majority of women."

In every case of a fibroid tumor of the uterus that I have ever studied I have found that the patient had for a long time suffered from various causes of ill health, or from abnormal conditions. This would seem natural, for there must be considerable disease before a fibroid tumor can grow or be developed.

On page 137 Williams remarks: "An enormous amount of literature has lately been published on the surgical treatment of myomatous tumors; but it appears to me that hardly any of those who have written on the subject have grasped the fundamental factors essential for arriving at a proper conclusion. Hence large numbers of women have been mutilated to no purpose, and many valuable lives have been unnecessarily sacrificed."

Here again, I think, Dr. Williams is greatly mistaken. The work of surgeons is everywhere most excellent. They do not proceed without due consideration; they do their work thoughtfully and carefully, and save many lives. I am glad to quote here from the brilliant address of Dr. W. D. Haggard at the first meeting of the Southern Surgical and Gynæcological Society. He says of the medical profession: "A body of men whose lives are devoted to mitigating human suffering and preserving human life—a profession glowing with benignant aims and illustrated by heroic self-sacrifice."[15]

Dr. Williams says his above remarks especially apply to those who have advocated and practised extirpation of the uterus for small myomata.

The smallest myomatous tumor I ever saw removed weighed, as above stated, less than one pound; but it was the greatest blessing to the patient that the tumor was removed as early as it was. Its early removal saved her a sad history of suffering. The operation was performed by one of the most eminent surgeons in New York City. I see occasion only to commend again and again the work of various surgeons. I only see cause for questioning imaginary theories and suppositions.

The smallest fibromyoma I ever removed weighed six pounds, and most assuredly it would have been infinitely better for the patient had it been removed a half dozen years sooner. The next smallest fibromyoma I ever removed weighed from seven to nine pounds, and if it had been removed a dozen years before, it would have saved the patient years of suffering. The largest myofibroma that I ever removed weighed about seventeen pounds, and it would have saved the patient years of misery and of suffering and immense possible dangers if it had been removed when it weighed one pound.

Joseph Price of Philadelphia says: "The safety is in early operating." Lawson Tate wrote me in 1886: "The whole gist of modern abdominal surgery lies in earnest and continuous plea for early interference. An excellent work lately published in London by Stanmore Bishop on "Tumors," says (page 313): "The only certain remedy is by surgical interference; that delay in resorting to this unnecessarily imports into the case its most dangerous complications." The author further remarks: "So much has been said in the past as to the responsibility under which any one labors who advises resort to such operations as that of hysterectomy that there is danger that we may forget the far greater responsibility which rests upon those who counsel delay until an operation, which earlier might have been a simple and safe affair, has become in consequence of their advice a most dangerous proceeding."

I now come to quote one who was my teacher, in whose laboratory I worked for many years—Dr. Charles Heitzman, a great pathologist and a profoundly learned man. By none of the authors referred to above have I seen a quotation from or the least reference to his writings, or his large work on "Microscopical Morphology of the Animal Body, 1883." In fact, I myself had never read a half dozen pages in his book and never read his chapter on "tumors" till after May 2, 1901. On page 468 Dr. Heitzman says: "Tumors are morbid outgrowths of living tissues. An exact definition is impossible, and Virchow himself has said: 'If we were to torture a person to the last degree of endurance, he would still be unable to tell what tumors are.' "

Dr. Heitzman further states: "We shall confine the idea of tumors to these formations only which by pathologists are termed 'neoplasma' or 'pseudoplasma," which originate without marked inflammatory symptoms and terminate without a typical end; while the inflammatory process is completed by the production of a cicatrix."

In this paragraph the author affirms "that these neoplasm as fibroid tumors originate without marked inflammatory symptoms." Here he at once and beforehand disclaims the idea that I am attempting to prove, and which I think is the fundamental fact. *I hold that fibroid tumors result and are developed only from tissues which by inflammatory action have been reduced to medullary material.* They can result in no other way. They are from medullary tissue which is the outcome of infection and inflammation.

Dr. C. Heitzman adds: "The best definition is undoubtedly that of A. Lucke, who says a tumor is a growth produced by new formation of tissue without a physiological termination."

On page 469 Dr. Heitzman makes the statement: "All tumors originate from indifferent or medullary elements, in nearly the same manner as that by which physiological tissues are produced."

Physiological tissues are not produced as the results of inflammation; they come or are developed by the life forces from the life material of the system; while fibroid tumors of the uterus, which are pathological products, originate from tissues which by some infection or microbic influence have been reduced to inflammation or to a medullary condition; and from this medullary or embryonal material is evolved the tumor or abnormal growth.

Dr. C. Heitzman says: "The reason why a tissue sometimes produces a tumor is not understood."

I say positively, the reason why a tissue produces a tumor is from some infection, in consequence of which the tissues are reduced to an inflammation, and from this inflammatory material the tumor is developed.

Dr. Heitzman says: "In some instances it appears to be due to long-continued irritation or to an injury; but in many instances no such cause can be traced."

Cohnheim asserted this in 1880, and many have since repeated it. I believe the reason why a tissue produces a fibroid tumor is that the tissues, from a previously inflamed condition, are reduced to medullary tissue or protoplasm; and from tissues so reduced any new growth may be developed.

Here the learned author of "Microscopical Morphology" does not give an intimation that a fibromyoma of the uterus comes from a diseased condition of the organ, that the tissues of the uterus are first necessarily in a diseased condition. When I removed a large myofibroma—the first total hysterectomy for fibroid ever done in this country—I studied the tubes and ovaries which were most profoundly diseased, in Dr. Heitzman's laboratory. The master of the laboratory never once remarked or intimated that the fibroid tumor came from a diseased condition of the uterus. Nothing was ever mentioned about the uterus being diseased, nor an intimation of it, nor did I hear him in any way give or refer to such a thought; nor have I ever heard it expressed by anyone till I stated it before the New York State Medical Society in Albany, January, 1901.[18] This great truth was forced on me by what I saw under the microscope."

Dr. C. Heitzman, apparently referring again to Cohnheim (page 482): "But in many instances no such cause can be traced; neither are we able to explain why the reaction following the irritation is in some individuals an acute or chronic inflammation only, and in others the production of a tumor in addition."

If the inflammation or infection is enough to reduce the tissues to their primal elements, it is in a condition to produce fibroid tumors or any abnormal growth. There will certainly result some changes of tissue. It may be only fibrous connective tissue will be formed. I hold that the only reason why a tissue sometimes produces a tumor is because the tissue is reduced to a medullary substance, and these life elements may develop into any formation, new growth, or tumor.

As I have repeatedly said and proved, a tumor can be developed only where there is an inflammation; and the tumor is the outgrowth of this inflammatory material that by inflammation has been reduced to an embryonal or medullary condition.

Dr. Charles Heitzman says in his work: "It is easy to explain the cause and formation of a tumor by the terms general diathesis, or general local disposition, but is there anything satisfactory in such an assumption? Is it not more correct to honorably admit that we do not know the real etiology of the tumor?"

Thus this great pathologist admits he does not know the real etiology of tumors. One of Dr. Heitzman's pupils who studied a long time in his laboratory has lately given me Dr. Chas. Heitzman's express views as to the origin of fibroid tumors. The following is the exact copy as written by the pupil of Dr. Chas. Heitzman, and as he repeated it in an article of his, published in a German medical journal:

"The origin of the myoma has to be looked for in the small arteries—a small vessel with thickened walls, especially in the muscular elements, with a decided thickening of the media, so much so that the lumen of the vessel is harder to be recognized from the starting point to myoma. Gradually a welding of the parts occurs, a small particle forms itself around this muscular knob, connective tissue is located with capillaries and small arteries, the latter undergoing the same metamorphoses; later new knobs are formed thereby, and lay themselves continually to the original knob. In one word, it is proliferation of the small uterine arteries, and next hypertrophy of the uterus, that forms the myoma." Is not this Kleb's theory?

I have in this article tried to present the views and theories of different eminent surgeons and pathologists as to the origin and formation of fibroid tumors of the uterus. It is a beautiful study, and demands our careful thought and consideration.

I have also ventured to present a theory. Studying the tissues of a number of cases of myomatous uteri, I found each one profoundly diseased; but these were all from my own patients. Naturally, I wanted to see the cases of some other physicians, and what would be the testimony of other uteri; but in no laboratory could I find prepared specimens of the tissues of the human uterus in proximity with fibroid growths. The great question with all seemed to be "the tumor"—not a word said of the condition of the tissues around the tumor, or of the condition of the uterus that contained the tumor. Even when attempting to speak of it to one or two eminent and learned pathologists, they did not seem to realize the point, but went on amplifying in regard to the tumors, the myofibroma, etc. Books have been written on tumors, telling their nature, form, growth, numbers, degenerations, etc., but nothing, so far as I have seen, said of the pathological conditions of the immediate or surrounding tissues, and not the least reference to the condition of the uterus where the tumors grew and were developed. This seemed to me the question of supreme importance. As I could find nothing on the subject, I commenced from the beginning, got various specimens, prepared and mounted them.[19] It has taken months to go over the whole ground; and while I have seen repeatedly new proofs, every specimen of the tissues of a myomatous uterus which I examined showed clearly long-existing disease, and indications that this disease may have caused the development and growth of the tumors. Yet, after seeing all these most impressive and marked demonstrations, I confess that I am not now more convinced of this great truth, the origin of fibroid tumors, than I was last October. I believed it then; I believe it now. I believe that this theory is in accordance with Nature's simple and beautiful laws, and that it will be still more confirmed by further investigation. I can only present the theory, with the proofs, for approval or condemnation. I shall be glad of more light.

SOME PRACTICAL PROBLEMS IN SOCIOLOGY SHOWN BY A STUDY OF THE SOUTHERN NEGRO.*

By M. L. PERRY, M.D.,
PATHOLOGIST TO THE STATE SANITARIUM, MILLEDGEVILLE, GA.

ACCORDING to the census of 1900, the total population of the United States is something over seventy-six millions. Of this number there are 8,840,789 persons of negro descent, over 90 per cent. of whom are residents of the Southern States. To come closer home, there are in Georgia 1,034,813 negroes out of a total population of about two and one-quarter millions. These figures show the important rôle which the negro must necessarily play in our social system, especially here in the South, and to what extent society at large may be influenced by the degree of his development. That the writers and students of sociology throughout the country have been awake to the importance of this subject is shown by the amount of literature which has appeared within the last decade treating of the "negro question." Much of this literature, however, either has had a political aspect or has dealt with the social status of the negro race as compared with the white race. I do not propose to touch upon either of these subjects. It is the object of this paper to present for your consideration certain conditions existing in the Southern negro which have a profound influence upon their development as a race, and thus upon society at large. These conditions are well known to the medical profession, but the laity should, I think, have a better knowledge of them.

First, I will call your attention to the prevalence of venereal diseases. The negro is notoriously lax in his morals. There is in his makeup a large endowment of animal passion, while judgment and the proper consideration of consequences are usually deficient. Having these natural proclivities, let him be placed in an environment where restraint is light and social caste does not depend upon virtue and chastity (and we know that this is the custom among the negroes in many sections) and what is the result? It can only lead to widespread and promiscuous sexual indulgence. Under such circumstances venereal diseases are always prevalent. That venereal diseases do exist to an alarming degree among the negroes in the cities and larger towns, is a fact that can be attested by any physician. It is true also that this condition has developed in comparatively recent years, certainly since the days of slavery.

There are two diseases, viz., gonorrhœa and syphilis, which deserve some special attention. They deserve special consideration because both of these loathsome maladies may be, and are at times, communicated to innocent individuals through the ignorance or carelessness of the person afflicted with them. Let a servant who, in the discharge of his or her duties, is thrown daily in contact with the members of a household, or a nurse who has the care of innocent and defenseless children, be afflicted with either gonorrhœa or syphilis, and there hangs constantly over that family a blight, like the sword of Damocles, ready to fall at any time upon some unsuspecting member. I know of no more distressing sight than to see a pure and guileless child suffering with a loathsome venereal disease. And yet such cases now and again come to the knowledge of the physician. This is a question which must necessarily appeal to us here, in this section of the South, where we have to depend almost entirely upon the negro race for our domestic servants.

---

*Read before the Georgia State Sociological Society at the annual meeting in Atlanta June 24-26, 1902.

The sociological influence of gonorrhœa is limited almost entirely to this question of its communication; but it is not so with syphilis. Here we have to deal with a disease which is insidious in its onset, obstinate in its course, persistent in its attacks upon its victim, and whose influence, like the iniquities of which we read in Holy Writ, may be visited upon the children unto the third and fourth generation. Syphilis at the present time is making inroads upon the negroes of the South, and its influence will be far-reaching in its effects upon the race. This is due, primarily, to the fact that the negroes rarely become cured of the disease. As a usual thing they apply for relief from certain disagreeable symptoms, and as soon as this is obtained they give up treatment. Some years since, while serving as interne in a hospital in a Southern city, I had abundant opportunity to note this fact. I remember but one patient who continued treatment for any length of time after the annoying symptoms had disappeared. Thus the negro who is afflicted with syphilis goes about for years, it may be, infecting others and procreating children weakened by inherited disease and unfit to assume their place in society.

Tuberculosis is another disease which has, in recent years, become so prevalent among the negroes as to justify the belief that it may soon be a veritable scourge to the race. The susceptibility of negroes to consumption has apparently undergone a most remarkable change within the last thirty of forty years. During the days of slavery the disease was so seldom found among them that they were considered almost immune to it. In fact, some of the older writers took that stand squarely, and asserted that consumption was unknown in the race. From being thus so rare as to be almost unknown, it has, in a single generation, become so prevalent and so fatal that now more negroes in the South are dying of tuberculosis than of any other disease. While it exists among all classes, it is in the densely-populated quarters of towns and cities, where they live in overcrowded and poorly-ventilated houses, that it is found to be most frequent. In institutions, where large numbers are more or less closely confined, the ravages of this disease are becoming truly alarming. In this connection it may be of interest to state that of the cases coming to autopsy in the negro department of the Géorgia State Sanitarium last year 50 per cent. showed some tuberculous involvement, and from observation and study of the subject for a period of three years, in that institution, I am of the opinion that this percentage may be considered a fair index of the existence of this disease in all our negro patients at the time of death. This high percentage is, of course, not applicable to the race in general, but it is a fact beyond question that tuberculosis exists widespread among the negroes of this section and, at the present time, is on the increase.

From the consideration of this state of affairs, two questions of great importance, from a sociological point of view, present themselves. They are first, what is its influence upon society, and second, what will be the effect upon the race? When we reflect upon the fact that tuberculosis is infectious and, under favorable circumstances, may be communicacated from one individual to another, and that its spread can be checked only by careful attention to personal hygiene, the answer to the first question must be apparent to all. We may safely say that nine-tenths of all the negroes afflicted with consumption are utterly ignorant of its communicability, and also, of the hygienic precautions necessary for its restriction. The influence upon society of a constantly increasing number of individuals, each of whom is a source of infection of one of the most dreaded and fatal diseases known to mankind, must necessarily be baneful.

The effect upon the race of such wholesale infection must also be bad. It has long been recognized in medicine that the descendents of tuberculous parents are below the normal standard in their resistance to disease. As this taint becomes more pronounced in the race. their physical development will suffer. Indeed, such a change has, apparently, already begun. The older writers upon the subject emphasize the fact that prior to 1860 the negro was a splendid specimen physically. The following quotation from a paper on the "Future of the Colored Race in the United States," published some years ago, by Dr. Eugene Corson, is interesting in this connection. He says, "All the information which I have been able to obtain has satisfied me that the race was a healthy one, even healthier in the main than the whites. Since the war things have been reversed; the colored race as a race is not a healthy and robust one; their vitality is in a state of unstable equilibrium, liable from any undue strain to give way." Statistics from institutions, having both white and colored patients, will show that the latter is less able to resist the onslaught of disease Dr. Mitchell, the superintendent of the Mississippi State Insane Hospital, in his last report says: "There is one great difference between the races as regards mortality, and although our treatment, both dietetic and medicinal, is the same our loss from deaths among the colored far exceeds that sustained by the whites." Let us see what the records of the State Sanitarium of Georgia show. From the report for the year ending September 1, 1900, we find that the death rate, based upon the total number under treatment, was 5.8 per cent. in the white department and 11.5 per cent. in the colored department. From the last report, being for the year ending September 1, 1901, we find a death rate among the whites of 6.7 per cent., while in the negro department it reached 17.1 per cent. During present year the ratio up to this time has been even greater, and this. despite the fact that their care and treatment is the same. These are facts not theories. They show that under similar conditions the negro at the present time offers less resistance to disease than does the white man, and, therefore, is a less stable specimen physically. To just what extent syphilis and tuberculosis are responsible for this weakened vitality in the negro it is, of course, impossible to say definitely. I believe, however, that the facts will warrant the assumption that their rôle has been a major one.

Turning from the physical condition of the negro, let us now investigate the mental stability of the race. Statistics, which are always more important and reliable than mere theories and opinions, show us here a most extraordinary state of affairs. They show us that since 1860 the negroes in this section, and the same is true of the South generally, have undergone such a change in their tendency to the development of mental diseases as is shown by no other people in a similarly short period of time in the whole history of mankind. I will take the statistics of our own State, Georgia, a typical Southern State, as they will probably be of more interest to this society than would those of the whole United States.

According to the census of 1860, there were in the State of Georgia forty-four insane negroes. The negro population at that time was 465,698. The ration of insane to the total population was thus 1 to 10,584. In 1870 there were 129 insane negroes in this State out of a total colored population of 545,142, or 1 to 4,225. In 1880 the census shows that there were in the State 411 colored insane out of a total of 725,133, or 1 to 1,764. In 1890, according to the census, there were in Georgia 560 insane negroes out of a population of 858,815, or 1 to 1,533. The census of 1900 gives the negro population of Georgia as 1,034,813. The bulletin giving the insane population has not yet been issued, but we can approximate very closely to what it will be. There were in the State Sanitarium on September 1, 1900, 799 colored patients, and from the number of applications for admission at that time we may safely estimate that there were, at least, 100 more insane in the State. Reckoning on this basis of 900, we find the ratio of insane to the total colored population in 1900 to be 1 to 1,149.

Thus in forty years the total negro population in the State has been a little more than doubled, while the number of insane has increased twenty-fold. No other such rapid and radical change in the mental stability of a race is recorded in history. Can anyone doubt but that the race has been weakened by it! This outburst of insanity becomes still more remarkable when we consider that for generations prior to 1860 the colored people had been free from mental disease. It has developed, therefore, without the slightest hereditary taint. What their condition will be at the end of the next forty years can only be conjectured, but considering the fact that the rising generation will have to contend with a marked hereditary predisposition from which their fathers were free, the outlook in this direction is certainly not encouraging. Even now the brain of the negro does not appear to be able to sustain a mental strain as well as that of a white man. This is shown by the fact, well recognized in asylum practice, that the colored insane tend to pass through the primary insanities and become demented more quickly than do the whites. A word or two upon the comparative brain capacity of the two races may be of interest here. I know of no statistics giving comparative brain weights in the sane, but I have taken for comparison the brains of 100 patients of each race dying insane. The following table gives the average brain weight in these cases, together with the average normal weight:

Average weight of normal brain in human male, 1,403 gms.; female, 1,247 gms.

Average brain weight in 100 white patients dying insane, male, 1,353 gms.; female, 1,197 gms.

Average weight in 100 colored patients dying insane, male, 1,229 gms.; female, 1,092 gms.

The average weight of the brain of the negro is thus seen to fall below that of the white man by something more than 100 gms, or about 3½ oz. It is true that the degree of intelligence is indicated more by the development than by the weight of the brain, but, other things being equal, the average brain weight of a race may be taken as an index of its mental capacity.

From the foregoing we see that within the past few decades there has been a decided tendency toward the lowering of the status of the colored race, both as regards physical condition and mental stability. Let us see if we can correlate these conditions and find what has been the cause of this radical alteration in the racial temperament. We have seen that they were remarkably free from that most important of all predisposing factors in the production of disease, viz., hereditary taint. They have been by nature likewise freed from cares and the harassing burdens of responsibility incident to business and public life. The mixing of the races has by some been offered as a probable factor in the weakening of the colored race. This is untenable, however, for among the insane, where such effect would be most likely to show, we find the full bloods far outnumbering the mulattoes. There is only one influence to which we can attribute their altered condition; that is, environment, which is applicable to both the physical and mental temperament. The sudden removal of those healthy restraints which for generations past had surrounded them during the days of slavery, was followed by the taking up of vicious habits of indulgence. The tendency to flock to the cities and towns, which has been and still is so pronounced with the negroes, has had a deleterious effect upon them. There they readily fall into idle habits, which are the breeders of vice and crime. It is in these overcrowded districts that syphilis and tuberculosis are found in greatest profusion. The laws of health and hygiene, which in the olden days were strictly enforced, are now too often neglected. Unless something can be done either by education or legal enactment to improve this unwholesome and pernicious environment, which to-day surrounds a large element of the negro race in the South, I can only believe that they will go on from bad to worse.

I cannot leave this subject without calling attention to one more danger which is threatening the negro at this time; that is, the drug habit. We are all of us more or less familiar with its bad effect upon the whites, but, believe me, if the colored people, with their strong natural bent toward the indulgence of the appetites, become the victim of drugs and yield to the subtle and delusive enchantment of opium and cocaine the result will be disastrous. There is nothing which has such a benumbing and perverting action upon the moral nature of an individual, to say nothing of the physical and mental effect, as the chronic poisoning by the use of these drugs. I am reliably informed that in some sections of the South their habitual use is already becoming prevalent. So far as I can learn, it has made little headway as yet in Georgia, but a start has been made. In Atlanta, until a few months ago, I am informed by good authority, the habit was decidedly upon the increase, and it had reached such proportions among the lower classes, to whom it seemed to be chiefly limited, that 75 per cent. of the women and 20 per cent. of the men coming to the station-house were addicted to the use of cocaine. Since the passage of a law prohibiting the sale of cocaine except upon prescription, the habit appears to be decreasing. This suggests the remedy, and it is our bounden duty, as the governing and controlling race, to protect these people by the enactment and strict enforcement of such laws in every State.

In conclusion, let me say that I do not wish to appear as an alarmist or a confirmed pessimist. I have merely presented some facts as they exist. If they are such as to warrant a pessimistic view upon the subject, then the quicker we realize it the better, that we may look about us for some remedy to apply.

Nor do I wish this article to in any way be misconstrued into an attack upon the Southern negro.

Far be it from me to cast any reflection upon those honest and honorable negroes who are living right and endeavoring to raise their race to a higher level. It is the erring and afflicted to whom this article refers, and it has been written only in the hope that through a wider knowledge of the facts some good might come to the negro race and to society at large.

DUST, DIRT, DAMPNESS, AND DARKNESS AS ETIOLOGICAL FACTORS IN TUBERCULOSIS.

By CHARLES R. UPSON, M.D.,
WATERBURY, CONN.

Notwithstanding that much has already been written upon this subject, I feel that its importance warrants reiteration, even though I present but little that is new.

According to Jaccoud, "the tubercle bacillus belongs to a class of pathogenic microbes called etiological dualisms, because they exist in healthy organisms indefinitely without injury to the latter, and become noxious only in consequence of changes in the organism itself from other causes."

A susceptibility to the action of the tubercle bacillus on the organism may be engendered by any cause which lowers its resisting power.

In this article I shall consider only the influence of dust, dirt, dampness, and darkness—the four D's of tuberculous propagation—in creating under certain conditions a predisposition to tuberculosis.

The dust from our city streets consists largely of finely-powdered animal excrement, minute particles of pulverized stone and vegetable matter, carbon soot, and other dirt—furnishing a means of transportation for millions of bacteria,among which the tubercle bacillus occupies a prominent place.

In large manufacturing centers, especially where large quantities of soft coal is consumed, we have less light and sunshine and a large excess of carbon dioxide in the air—two potent factors in the causation of tuberculosis.

This bacilli-laden dust and dirt is constantly in the air, especially in the cities and large towns, and the inhabitants of such localities are taking it by inhalation into their systems. While it is true that in nose-breathers but a comparatively small amount of dust may reach the lungs, in mouth-breathers the reverse is true.

As stated, the healthy organism presents an unfavorable soil for the nourishment of these germs, hence their involuntary hosts are and remain immune until from some cause the organism becomes less resistant to their action.

The inhalation of dust and dirt is harmful not only in its direct irritant action on the mucosa of the respiratory tract, but also by the introduction of living bacilli.

The irritant effect of inhaled dust is largely spent upon the mucosa of the upper-air passages. This irritation first causes a hyperæmic condition of the nasal mucous membrane, which sooner or later, if unrelieved, causes hypertrophy of the turbinates, with more or less nasal stenosis.

A careful study of this subject warrants the assertion that turbinate hypertrophy is more prevalent in cities than in the country towns and, furthermore, these cases occur most frequently in cities having the largest mileage of macadam paving, which supplies a large amount of exceedingly irritating and infectious dust. Individuals thus affected become shallow breathers, and in some cases the elasticity of the lungs is considerably diminished, thus inducing a condition favorable to tuberculous infection.

Investigation of a large number of cases of latent tuberculosis* has convinced me that nasal irritation and obstruction often cause a predisposition to tuberculosis—in which statement I feel assured that most rhinologists will concur. Early treatment, therefore, especially in children, is a necessity. In some cases of nasal obstruction the mucous membrane becomes eroded by the inhaled gritty particles, by which channel the tubercle bacillus may gain entrance to the system. I have seen in my practice a number of cases of tuberculosis, in which the initial lesion, situated on the nasal septum, was caused as above mentioned.

The inhalation of street dust is also a prolific source of bronchial irritation and catarrh, which increases the susceptibility of the mucous membrane to the action of the tubercle bacillus.

Every physician located in a city or large town, especially where the streets are macadamized. has doubtless noticed the large number of patients seeking relief after a dust storm for coughs and sore throats, and he must also have observed that his tuberculous patients, even if confined within doors, are not progressing as favorably as before the storm. The irritation from inhaled dust and dirt is particularly distressing to the sufferers from laryngeal tuberculosis. It is often remarkable how great the improvement is in some of these cases after the removal of the patient to a cleaner locality.

The penetrability of dust, of even greater density than that of dried tubercle bacilli, into the air cells of the lungs is no longer a mooted question. I have repeatedly demonstrated such to be the case—dust particles having been found to have penetrated even to the air cells of the apices, where the air does not enter as freely as in other portions of the lungs. To illustrate:

1. A tuberculous patient, whose work had formerly been coal screening, brought to me, three weeks after ceasing work in the coal yard, the sputa from a recently-opened cavity—situated just below the left clavicle—from which I obtained, by washing, an appreciable quantity of coal dust.

2. I confined a large water-rat for two days in a well-ventilated tin box, through which at frequent intervals I forced a cloud of coal-ash dust, of about the same density as that which may be encountered in the street on a windy day. In the air cells of its lungs was found a considerable quantity of the ash dust.

Another case, showing how readily a rather heavy dust can be taken into the bronchi, may prove of interest.

A patient suffering from bronchial catarrh, who was at the time engaged in shoveling sand, at my request, furnished me with his sputa—accumulated between the hours of 10 P.M. Saturday (ten hours after leaving his work) and 10 P.M. Sunday. From this quantity (five ounces) I washed out ten grains of sand.

I have already referred to the insanitary macadam pavement as a place of lodgement and a means of distribution of the tubercle bacillus. In my judgment the macadam pavement should be abolished from our city streets. In its place should be laid, wherever practicable, the more cleanly and esthetic asphalt pavement, which can be kept thoroughly cleansed by frequent flushing from the street hydrant. If for any reason this kind of pavement cannot be adopted, the authorities should keep its principal streets well sprinkled.

Mr. Richardson says: "The best evidence of the desirability of asphalt surfaces, from a hygienic point of view, is offered by the death rate in various cities as compared with the class of pavements which are in use in them and the degree of cleanliness practised.**

---

*Upson, "Latent Tuberculosis." Medical Record, July 20, 1901, p. 94.

The following list of cities furnished some interesting data:

Berlin:	Almost all asphalt pavements; death rate per 1,000 inhabitants per year	19.6
Amsterdam:	Stone and asphalt; streets washed	20.
Rome:	Streets nicely cleaned; hard climate	21.2
Vienna:	Little asphalt; much stone and macadam	24.3
Dublin:	Granite, cobble, and macadam; fairly cleaned	29.3
St. Petersburg:	Cobble and macadam—notwithstanding cold climate, which kills germs	30.
New York:	1892; with little asphalt	38.37
New York:	1894; more asphalt	30.
	1896; more asphalt and cleaner streets, because easily cleaned	26.

In addition to the above data it is of interest to note that the death rate from bowel complaint in New York City decreased from 11.5 per 1,000 in 1892, to 6. per 1,000 in 1896. This increase is directly connected with the paving of the tenement-house district on the east side of New York with asphalt, and also to the increased cleanliness of the streets, which was possible with this form of pavement."

By the use of proper appliances for street cleaning much discomfort and danger from infection would be averted. There is a large field open in this direction to inventive genius.

Peter Green, a former street inspector of Chicago, has invented what he claims to be a dustless street-sweeper. It is run by a gasoline engine, which also operates a system of fans and suction-tubes by which the dust is gathered into proper receptacles. If his claim is substantiated, the name of Peter Green should be placed upon the list of public benefactors.

Dampness of the soil is another important factor in the causation of tuberculosis. The occupants of damp, mouldy buildings are particularly liable to contract the disease; hence, proper prophylaxis in these cases should embrace thorough drainage of the subsoil, the removal from the cellar of rotting wood and decaying organic matter, together with proper cleansing and the free admission to all portions of the building—especially the cellar—of air and sunlight.

That darkness should be a potent agent in causing a predisposition to tuberculosis can be readily understood, and therefore needs but brief mention. We know that while dampness and darkness are prejudicial to man the same conditions are favorable to the tubercle bacillus.

In the Eleventh and Thirteenth Assembly Districts in New York out of 50,640 rooms in apartments there are 17,015 having no outside windows. The inference is clear. Think of it—one-third of these rooms with no means for the admission of either air or sunshine, nature's germicides.

It may not be amiss to refer here to the old superstition, especially in vogue in the country, that air and sunlight should be excluded from the sick-room. This belief should be done away with. There is certainly no place where the cheering and vitalizing effects of air and sunlight, not to mention its valuable germicide qualities, are more needed than in the sick-room. By all means give the sick—protected, if need be, by a screen—an abundance of pure air and sunlight.

Sanitary measures for the prevention of tuberculosis should embrace the suppression of the spitting and dust nuisances, the adoption by the authorities of regulations providing for the sanitation of tenement-houses, especially with reference to the size of the rooms and the free admission to them of air and sunlight.

Squires believes that laws should be enforced regulating the width of streets, the amount of open space around the houses, and the size of windows; also that efficient inspection should be carried out before they are allowed to be occupied.

If these suggestions could be effectively carried out in all cities and towns it would result in a material reduction of the mortality from infectious diseases. The homely adage that "an ounce of prevention is worth a pound of cure" is strikingly true in its application to the prevention of disease.

In many cities the sanitary authorities are already caring for the sanitation of the tenement-houses, which has been productive of much good. The editor of the MEDICAL RECORD, in an editorial on an interesting article—"Sanitary Motes and Beams," by Dr. Gihon§—says: "No city can be accounted clean until its ordinances require every cellar-door to be widely opened to sun and air—that royal pair of germicides; every cellar to be emptied of its refuse; every cellar wall and ceiling to be scraped and whitewashed; every cellar floor to be taken up, if rotted, and sprinkled with lime if uncovered—a tedious and expensive process; but efficient sanitation, costly as it must be, is cheap compared with the outlay of a single epidemic. There are underground foulnesses in all our great (and many of our smaller) cities, of which they should be rid at any cost, as where rag-pickers and bone-gatherers collect their filthy stores, and Italian street-corner fruit dealers keep their decomposing bananas, grapes, and oranges till, rubbed off by dirty handkerchiefs, they are exposed for sale, glistening after their repulsive polish with impure saliva."

The number of deaths from tuberculosis—a preventable disease—would seem an indictment of the people, the authorities, and, might I not say, of the medical profession as well.

In a paper—"The Prevention of Phthisis,"§§ read by Dr. Squires before the London Epidemological Society—reviewed by the editor of the MEDICAL RECORD, the author says: "As the effects of phthisis in the individual are not confined to a single generation, but are handed down by hereditary transmission from parent to child, any cause which tends to increase tuberculosis among the adult population must be regarded as tending to produce a progressive deterioration of race. It is, therefore, to the interest of the community to allow no time to be lost in commencing a systematic attack against preventable causes of phthisis."

In conclusion, let me express the hope that I have at least briefly indicated the primary cause in many cases of tuberculosis.

Intravenous Injections of Bichloride of Mercury and Other Salts.—Nicola Cerri, considering the Baccelli method of the intravenous injection of corrosive sublimate in apparently hopeless syphilitic cases, says that it has finally triumphed over skepticism and bitter objections and may be considered one of the great achievements of modern therapy. Baccelli has recently suggested its use as a remedy for *aphtha epizootica*, as he considers aphtha to be a true septicæmia of 141 bovines affected by aphtha and cured by the Baccelli method in the Grand Duchy of Hesse, not one manifested symptoms of mercurialism, and of 177 treated in Bavaria only three showed any such symptoms. Injections begun in the prodromal stage when the chief symptom is elevation of temperature are the most efficacious.—*Cleveland Medical Journal*.

OUT-OF-DOOR TREATMENT.

ITS SPECIAL RELATION TO THE PREPARATION FOR AND CONVALESCENCE FROM OPERATIONS.

By N. B. ALDRICH, M.D.,
FALL RIVER, MASS.

Realizing the necessity of thoroughly knowing the condition of a patient that is about to be operated upon and the value of preparation for operations, I feel that the time is ripe to consider one great fault in the methods, as usually practised, to better the condition of patients before and after operations.

It often happens that the patient is one accustomed to lead an active life. He enters the hospital and is put to bed to be prepared for a given operation. If I wanted to grow vigorous and become prepared for any extra tax on my system, I would never think of remaining in bed any length of time. I should try and live an out-of-door life that would be conducive to robust health, taking proper hours for sleep and rest. Too often in the preparation of a patient for abdominal operations, for instance, all that is considered is the opening and emptying of the bowels and the investigation of the conditions of the other organs. Patients are too often put to bed and kept there for one or more weeks before the operation is performed. Is this patient becoming more resistant or less resistant? Cannot the same careful preparation of the viscera, etc., be obtained and the patient still have a reasonable amount of out-of-door exercise and fresh air? Would a prize-fighter make better resistance to an attack in the ring after lying in bed a few weeks?

I do not believe it necessary or wise to confine the usual patient in bed for more than one day, and in certain cases I confine him for only part of a day. Do not misunderstand me, I do prepare my patients by regulating their habits for a week or more before an operation, but do not believe in long bed rest. If the surgeon knows his patient's condition to be excellent, one day's preparation is better than two weeks in bed. I remember well a machinist who was a sufferer from recurrent appendicitis. I operated on him between the attacks with only one night's preparation. I found a large abscess of the mesoappendix well walled off by adhesions, removed the appendix and mesoappendix, including the abscess cavity, closed the abdominal wound without drainage, and in just two weeks discharged this patient not only well, but very well. I ask the reader of this article if this patient's condition would have been better if he had had two weeks bed-rest before the operation? This is but one instance: I could cite many others.

I insist that fresh air, out-of-door exercise, and proper hours for rest are of as much importance in preparing the patient as enemas, cathartics, baths, etc. So much then as to fresh air in the preparation of the patient.

In convalescence it is of equal importance. I have had patients up in six days after operations for appendicitis. , Five out of the last seven patients I operated upon for this disease were out of doors walking around in from nine to fourteen days after the operations, and I believe their rapid return to good health was helped by this out-of-door treatment.

How often have I seen a poor fellow lying in bed after an amputation of an arm or leg, kept there four or more weeks even when the flaps were healing by rapid union. Will any one tell me why, if such a patient is doing well, if his temperature is normal, his pulse good, and union is taking place by first intention, he should be kept in bed more than three days? I recently amputated a forearm (emergency case) at my hospital, sent the patient home in my carriage, immediately after the operation, and had him return on the fourth day and every two or three days thereafter. This patient did not put on that pinched look that the bed-ridden patient does, and I believe regained his strength in one-half the time he would have had he been placed in bed. It seems to me a good rule in most hospitals would be to learn the patient thoroughly, make the preparation of the patient of sufficient length, give the patient out-of-door exercise as long as it is possible before the operation, and as soon as it is possible after the operation. Bed-ridden patients make slow recoveries.

TREATMENT OF ULCERS OF THE LEG.

By CASS CHENOWETH, M.D.,
DECATUR, ILL.

The following is my treatment for ulcers of the leg. In ulcers not larger than a dollar I have the patient put the leg in hot water for an hour, then wash with soap and clean water, dry the leg, then wash with a weak formaldehyde solution, dry thoroughly and dust ulcer with boracic-acid powder. Now I take strips of rubber adhesive plaster one-half inch wide, commence back of the toes, and apply tight, overlapping each lower strip, up to the knee, then apply an ordinary roller bandage. I allow this dressing to remain until the discharge shows through, which it will do in from five to seven days, and then the whole dressing is taken off and the ulcer cleansed as before, and a clean dressing applied. This will usually remain for about two weeks, when it is removed and the wound is dressed as before. These ulcers are generally well in six weeks' time. In cases in which the ulcers are larger than a dollar, I send the patient to bed for two weeks with instructions not to get up except to empty the bowels and bladder. While in bed I have the patient use a moist dressing of one ounce of boracic acid to one quart of water.

Unless the ulcer is very large, the two weeks' rest will reduce it so that it can then be treated as a small ulcer, but if two weeks is not long enough I I keep the patient in bed two weeks longer, although this is very rarely required. As soon as the plasters are applied I allow the patient to follow his usual occupation. After the ulcer has entirely healed I have the patient wear an elastic stocking.

Kataphraxis.—A Catterina applies this term to a method he has devised for the treatment of ectopic organs, and which consists in fixing the displaced viscus in a metallic frame work or cage. As first described and practised, the operation was applied to the kidney, but the author has since used it for prolapse and retrodisplacements of the uterus with equally good results. Th usual incision for ventral suspensions is made somewha to the left of the middle line, and the uterus is drawn forward and out of the wound. A wire of gold or silver is then passed about the organ at the level of its lower third by perforating the broad ligaments on either side. The tw ends of the wire are carried through the entire thickness of the abdominal wall, with the exception of the skin on either side of the incision. A similar suture is carried behind the uterus, just below the point of attachment of the round ligaments These sutures are then tightene to the degree necessary to bring the uterus up into position, and their ends joined on either side of the abdomina incision, the right upper wire being twisted with the right lower one, and the left upper with the left lowe one, so that the midline of the body is not crossed. In some cases a single wire suture may be used, and then it ends are united over the line of stitches closing the abdominal wound.—*Centralblatt für Gynäkologie*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.
THOMAS L. STEDMAN, A.M. M.D, ASSOCIATE EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 30, 1902.

THE QUESTION OF INFECTION IN TUBERCULOSIS.

Since Koch made his statement that animal tuberculosis was not transmissible to man numerous experimenters have taken issue with him. It was certainly a shock to the many who had so gladly adopted the convenient theory that the contrary was true, but more especially were they chagrined that their theory should be combated by one who was popularly supposed to be the highest living authority on the subject. The health authorities who had formulated rules on other premises were likewise concerned lest their laboratories should have less work and their cattle inspectors be reduced in number. It was not so much the principle that diseased milk as such should not be used for food, as that bacteriological research for the public good should come under the ban of disparagement, and the motives of political scientists be open to suspicion.

So far, the theory which Koch promulgated appears to have held its own. This is in part due to the great difficulty in disproving his claim by any direct and conclusive experiments on the human animal. This was quite recently exemplified in the case of a young woman whom a physician was said to have inoculated with tuberculous matter from a cow, and who subsequently became infected with the disease. The daily papers gave the freest possible account of the exploit, and for a time the disputatious innovator was in the high light of public recognition. It was found, however, that neither the cow nor the girl had tuberculosis. The apparent aim of the experimenter was to advertise his special remedy for the cure of the disease.

The latest reports are to the effect that a French medical man has injected tuberculous material into his body, and is confident in his belief that he will triumphantly disprove the Koch view. It is to be hoped that the mortification of eventually failing to establish his point will be effectually offset by saving what may eventually prove, even against heavy odds, to be a valuable life. There is no great likelihood that his example will be generally followed, inasmuch as it is death to win and disgrace to lose. Thus the question is destined to be an open one for a long while to come. In the meantime there is no special reason why tuberculous meat or tuberculous milk should be used as food, as esthetic, if not scientific, arguments are sufficiently strong to guard us against even the faintest probability of infection from such a source.

In fact, in the study of the question of communicability of tuberculosis, in its broader aspects, it is quite evident there is much to be learned. The bacillus is not everything. The clinician must needs view its importance from a standpoint different from that of the bacteriologist. The latter studies the microbe; the former studies his patient. With one the bacillus is the prime factor in disease causation, but with the other it is an incident. The physician knows that the bacillus cannot of itself induce tuberculosis. If the patient does not give the soil, the seed can never take root.

When the microorganism was first discovered, it was at once declared that phthisis must be contagious, in spite of overwhelming facts to the contrary. It was the hue and cry of health boards over the entire country, and all sorts of promises were made to the public to stamp out the disease by killing the dreadful germ—as if that was the only thing to do. Here was an entirely new field in which the bacteriologist could work independently of the ordinary doctor, and for a time he was much in the fore. When a reaction came, contagion suddenly changed its name to infection, and in order to reconcile facts with theories, it was admitted that a person to become infected must be necessarily receptive. It was merely explaining the natural spread of the disease in a different way from that observed from time immemorial. It was the old-fashioned consumption plus the bacillus. As it was formerly, those predisposed to the disease take it and those not receptive escape. The bacillus seems to be necessary only when the patient is ready to receive it. From this point of view, the bacillus, as such, loses much of its former importance as a distinctly causative factor in an otherwise very complex process. In fact, the leading authorities on tuberculosis of to-day lay the greatest possible stress on increasing the resistance of the patient rather than in futile efforts to kill all the microbes. All this, it is true, is a slight to the bacillus, but it is about time for the practitioner to begin to think for himself, and explain in a rational way why one patient under like conditions gets tuberculosis and the other escapes, infected sputum, bad air, and bad food to the contrary notwithstanding.

If we go a step farther, we may be almost ready, in a certain sense, to take sides with those who maintain that the bacillus is rather the result of a primary predisposition to tuberculosis than the initiative cause of it. Certain it is that the microbe is inert unless the patient prepares the way for its invasion. Logically, then, it may be safe to say that the patient is the primary factor in the equation of chances. By killing the bacillus outside the body, we thus tackle the weaker side of the argument, in that all persons are not susceptible to its influences; and in many cases we are forced to assume a negative proposition of preventing an infection that may never happen, in any given case.

The case is entirely different when we strive to destroy or dislodge the invading microbe. Here, alas! no definite progress has yet been made—along those lines, for instance, that have been followed so successfully in the antitoxin treatment of diphtheria. With regret must it be said that there is yet no specific medication for the destruction of the bacillus or of its toxins. The old-fashioned methods are still in vogue. We give the patient fresh air, an outdoor life, sunshine, good food, and tonic treatment, and say that consumption is as curable as ever by such means.

THE VALUE OF NOTE-TAKING.

When it is acknowledged that nothing is more valuable in the practice of medicine than experience, it is strange, indeed, that note-taking of cases is not more a habit among all classes of practitioners. The opportunities are abundant enough, if they are only seized and utilized.

Facts of themselves are always of value, no matter what their interpretation may be. Aside from making them a matter of permanent record for ready reference, there is the training of accurate observation of detail which cannot be gained in any other way. Their systematic arrangement makes the accumulation of trustworthy statistics possible, and helps to establish many of those fundamental principles upon which the pathology and treatment of disease must necessarily depend.

To trust to mere memory under the circumstances is to foster a disposition for loose generalizations and unreliable data. Especially is this the case with those ordinary details that in the end are the essential points of difference when they are presented in sufficient numbers for general comparison. Take for instance the pulse and temperature curve in certain epidemics of typhoid, and in different cases of appendicitis. It is only by attention to such details that exceptional cases can be recognized and the physician or surgeon can be on his guard against a fatal error in diagnosis.

Then, too, each clinical picture should be worked out in all its details, whether particular symptoms may seem to have any special significance or not. Even in the rarer diseases their associaations become fixed in certain relations that necessarily in time force themselves upon the attention of the student.

From such a point of view each symptom becomes a sign for something that calls for explanation. Such a training makes the study of any case, however common, most interesting and instructive.

It is the reason why that appeals to the careful observer. Nothing is too trivial for his attention. John Hunter, who was a champion note-taker in his day, followed this practice, as did Sir James Paget, Sir Benjamin Brodie, George Bright, Peyer, Addison, Graves, and others, who have created new names for diseases and formulated new rules for their diagnosis. If Hippocrates had neglected to give his classical description of the moribund face, his name would not have been associated for centuries with a well-recognized phenomena of dissolution. It was the accuracy of description that left nothing more to be desired.

No matter what may be said of the value of mere book learning, there is nothing in the whole compass of human knowledge that equals the application of given principles to individual needs. Thus the observer must work out his own problem in his own way. There is certainly no better method than in studying the cases that are before him and in making accurate details of what he sees and needs to know. It is often the note on the spot that settl all after-doubt.

Those who are devoted to special study unde stand the true value of recorded phenomena. It the getting of all out of a case that is possible. Th method of study tends also to give the widest rang for observation, and prevents the riding of hobbi which more limited observation engenders. stimulates the search after the whole truth irr spective of theory and makes the student impartia critical, logical, and liberal. When these conditior fulfilled the accuracy of the picture can alway be recognized by workers in the same line.

The difference between the superficial and tl accurate man is always recognized on those line whether he recites his case before the Society publishes it in the journal.

A distinguished medical teacher has said th "the profitable study of individual cases is rightl based on the appreciation of exceptions to gener rules." In the textbooks we have the stereotype phenomena of disease presented, but in the study disease by the bedside we must note what we fin rather than vainly search for what we may expec Thus Paget wrote a very interesting book treatin solely of the curious and rare forms of disease man festation which he had studied, and, best of all, h knew they were unique in their way. Until he ha his attention drawn to the frequency with whic eczema of the nipple preceded cancer of the breas no one had thought of such a relation of cause an effect.

The question that must present itself to ever busy man with his many opportunities is wheth the thing is worth the trouble. To this questior however, there is but one answer.

Medical Trusts.

The formation of a Witch Hazel Trust wit $4,000,000 capital is one of the signs of the time that will appeal to the medical profession.

Omnibus articles of incorporation authorize th company to engage in any line of business. Th articles state specifically, however, that the con pany will manufacture, distil, and sell extracts witch hazel and other products of the distillatio of any kind of wood, and deal in soap, lotions, lin ments, and other articles manufactured in the whol or part from the by-products, distillation, or th manufacture of the same.

Thus all minor wounds, bruises, mosquito bite and the like can be treated in job lots to suit th demands of the public for free medication. Ne we may hear of an antitoxin trust, cod-liver o combine, and quinine monopoly, which may do fo the retail prescriber what the larger corporatior have done for the retail dealer. But have we no been approaching this condition of affairs in othe directions by cheap and wholesale prescribing o the part of hospital dispensaries with a dollar pe month fees, with free treatment in the numerou dispensaries and clinics, with million-dollar as lums for indiscriminate obstetric practice and fre care of tuberculosis cases by State and municipa authorities. Fortunately, as there is enoug sharp rivalry of individual interests to stimulat active competition between the different philar thropic bodies for serving the public, there is sti some hope for the poor medical man without polit cal, social, or college pull to keep his place and b content with the crumbs that accidentally fall from the various tables. But then the medical man nowadays has no business to be poor or without influence.

A Disputed Professorship.

Dr. Schweninger, who treated Prince Bismarck to reduce that statesman's flesh, has been appointed Professor of the History of Medicine at Berlin University. Prince Bismarck was so grateful that he tried to have Dr. Schweninger appointed nearly twenty years ago, but university circles raised a protest. Dr. Schweninger was Bismarck's physician up to the time of the Prince's death, living at Friedrichsruhe. Medical professors of a number of universities are circulating a protest to the government against the appointment, asserting that Dr. Schweninger has never written on or taught the subject of medical history.

If similar tests were applied in this country, how many professional chairs in some of the closely-corporated colleges might be vacant? One reason, perhaps, for the opposition in the case of the distinguished obesity expert is that the title of Professor in Germany is a much more restrictive and significant one than it is here. At all events, Dr. Schweninger before he gets through with his fight may have opportunities of reducing his own weight other than by his own methods.

Sanitary Matters in Cuba.

Officials and others returning from Cuba bring very contradictory reports as to the sanitary condition of the island since the inauguration of the new government. Some say that the natives are rapidly lapsing into their old ways of throwing slops and refuse into the streets, and predict that it will not be long before conditions will be as bad as under the old Spanish régime. Others say there has been no deterioration. The sanitary report of Havana for June is very satisfactory, although there was a slight increase in typhoid fever and in intestinal troubles among young children. Dr. Finlay can, of course, be depended upon to maintain a satisfactory sanitary condition in Havana if his hands are not tied. It is reported, however, that the authorities have abolished the Stegomyia and Anopheles brigades organized by Major Gorgas, and if this is the case it is merely a question of time before yellow fever comes back to stay.

Liver Abscess and Malaria.—James A. Hislop states that, in his experience in Assam, where dysentery is so common, cases of liver abscess are extremely rare. In three years, working among nearly 9,000 people, he has known only two cases of liver abscess. These patients had not suffered from dysentery within the three years preceding the development of the abscess, and the latter could not thus have been a sequel to dysentery. Hislop thinks that the dysentery of Assam does not tend to the formation of abscess formation, as it appears to do in other localities. Assam has a reputedly malarious climate, and in the two cases already mentioned the writer thinks that malaria was the sole cause of the abscess, while the predisposing factor was a drinking bout. He agrees with Sen, who says in his "Thesis on Tropical Abscess of the Liver": "Of all the cases of liver abscess in Bengal, by far the majority are traceable ultimately to malaria. Cases of liver abscess from pure malaria are generally associated with enlargement of the spleen. In this country drinking, combined with malaria, is the main cause of suppuration in about 80 per cent. of liver abscess cases."—*Indian Medical Record.*

News of the Week.

The President's Physician.—The announcement is made that Dr. George Augustus Lung, Surgeon, United States Navy, has been ordered to duty as Surgeon to the President to succeed Dr. John F. Urie, who was made Assistant Chief of the Bureau of Medicine and Surgery. Dr. Lung was born in New York and entered the naval service in 1888. He has been on waiting orders in this city, having been detached from active service last December.

New Public Baths.—Plans have been filed at the Bureau of Buildings, Manhattan, for three two-story brick public baths to be erected near One Hundred and Ninth street and Second avenue, on Allen and Rivington streets, and Forty-first street and Ninth avenue. They are to be constructed as follows: On the first floor there will be separate waiting rooms for men and women and separate baths for both. The men's bath will have thirty-four showers and two tubs, the women's twenty-nine showers and six tubs. The second floor will be given over to the men for baths with thirty-eight showers and two tubs. The building will be constructed with brick, terra cotta, stone, marble, and copper. The front will be of ornamental iron work, brick, white Italian marble and granite, with two entrances, one for men and one for women. The three baths will cost $225,000.

Insanitary Condition of the Subway Works.—The Board of Health has called the attention of the Rapid Transit Commission to the insanitary conditions prevailing along the line of excavations for the underground road. It is said that in many places sewers have been disconnected and are leaking, stagnant water is allowed to remain, and much refuse is dumped into the excavation. The communication is based upon a report of Sanitary Superintendent Roberts, which was made to the Board after an inspection of the excavations at various points. One, and not the least of the nuisances created by the carelessness of the contractors and their workmen, is a plague of mosquitos, the pools of stagnant water affording ideal breeding-places for these pests.

An International Congress on the Care of the Insane will be held in Antwerp September 1 to 7. The discussions will have special reference to the system of boarding out lunatics in families. The Belgian Minister of Justice is the Honorary President of the Congress, and the Acting-President is Dr. Peters of Gheel. Visitors will have opportunities of seeing the boarding-out system in operation both at Gheel and at Lierneux.

The Licensing of Prostitution.—Dr. E. Benjamin Andrews, Chancellor of the University of Nebraska, in the course of a lecture recently delivered at the University of Chicago, advocated a system of surveillance and licensing of prostitutes. He defended the method followed in Paris and elsewhere on the ground that the State is under obligation to take measures to protect innocent women and children and future generations. He dissented from the assertion as generally made that in granting a license to a person engaged in a business or practice which is looked down upon or scorned by people generally the authorities are entering into collusion with the persons licensed. There are many times he believed, when a license is the best and most effective method of suppressing or regulating a vice.

A Contortionist and His Medical Purchasers.—A man in Massachusetts, who was famous in his day as a contortionist of remarkable flexibility, several years ago sold his body (the goods to be deliverable after death) to a Detroit physician, who was anxious to study his skeletal formation; but after paying the money the physician died, and the heirs threw away that part of the estate as of no value to them. Another deal in futures was then made with a New York physician, but he also died. The contortionist, who is now nearly eighty years old and in excellent health, is said to be looking around for another purchaser.

Dr. Eduardo Porro, Professor of Obstetrics at Pavia and Milan died the latter part of July, at the age of fifty-nine years, after a long illness. It was he who first gained acceptance for amputation of the uterus in Cæsarean section, an operation that had considerable popularity a score of years ago and which was called by his name.

Remodelling the Old Bellevue Medical College Building.—Plans have been filed with the Building Bureau for the reconstruction of the old Bellevue Medical College building in the Bellevue Hospital grounds on Twenty-sixth street, east of First avenue. New fireproof floors and partitions are to be built and the building changed into a dormitory and dispensary for the hospital.

Dr. Henry D. McCormick, house physician in the Branch Hospital for the Insane at Overbrook, N. J., has tendered his resignation to the Committee on County Hospitals of the Board of Freeholders. It is thought that Dr. Robert Bolton, who for several years has been on the staff of the County Hospital for the Insane in Newark, will be appointed to fill the vacancy.

A Naval Medical School.—Surgeon-General Rixey has under consideration plans for the establishment of a school for the special training of newly-appointed assistant surgeons in the Navy, similar to the Army medical school, which has been for several years in successful operation. It will be established in connection with a new naval hospital to be located on the site of the Naval Observatory in Georgetown. The medical school will really be an adjunct of the hospital, though no new buildings will be needed for that purpose. The instruction will be in case-taking and the keeping of the medical log, and much attention will be paid to practical laboratory and bacteriological work, the course occupying several months.

Smallpox in Barbados.—It is reported in cable despatches that smallpox is epidemic on the Island of Barbados, and is spreading rapidly in spite of the efforts of the health authorities to check it. Vaccination is being urged, but many of the negroes oppose it, and a panicky feeling is growing among them. Most of the neighboring islands have declared quarantine against Barbados.

Wholesale Importation of Trachoma.—Eighty-five cases of trachoma were found among the steerage passengers of the French line steamship *La Gascogne* and the Red Star liner *Zeeland*, which arrived at the port of New York this week. There were sixty-five cases on the former and twenty on the latter. The persons affected are mostly Syrians, Roumanians, and Austrians. The only penalty for such attempted importation at present is deportation at the expense of the lines, but under the proposed new immigration act, which has not yet become a law, a large fine may be imposed upon any steamship company bringing diseased passengers to this port.

The American Dermatological Association.—The twenty-sixth annual meeting of this association will be held in Boston on September 18, 19, and 20, under the presidency of Dr. George Thomas Jackson of New York. The secretary is Dr. Frank Hugh Montgomery of Chicago. A general discussion on "Acne Vulgaris" will take place at the second day's session.

The Gynecological Service at the Johns Hopkins.—Dr. Howard A. Kelly of Baltimore has donated $10,000 toward an addition to the gynecological ward of Johns Hopkins Hospital.

Enforcing the Mosquito Law.—Winchester, Va., has an ordinance looking toward the repression of the mosquito nuisance, and the officials seem to be determined that it shall not be a dead letter. One of the prominent residents of the place, a brother of the Mayor, was recently arrested for failure to comply with the provisions of the law in not covering the water in his rain-collecting barrels with kerosene oil.

The Doctors' Protective Association of Kentucky recently filed articles of incorporation at Frankfort. The object of the association, the incorporators of which are not themselves medical men, is to collect accounts for physicians or to purchase them outright, and to furnish information to practitioners regarding the ability or willingness of patients to pay for medical attendance.

Dr. Samuel Patterson Stafford, a colored physician of St. Louis, has been appointed the government physician at the Yakima Indian Agency, in the State of Washington.

A Tuberculosis Sanatorium Closed.—The proprietor of a private sanatorium for consumptives, which was running for a few weeks in a New Jersey suburb, suddenly closed the doors of the institution one day last week, and forced all the patients to find new quarters as best they could with the briefest possible notice. The place is said to have been conducted with absolute disregard of modern scientific teaching, and the Board of Health interfered for the protection of the community.

Unveiling of a Statue of Pasteur.—On August 3 a statue of Louis Pasteur was unveiled at Dôle. M. Trouillot, the Minister of Commerce, presided, and among those present were the Rector of the Academy of Besançon, representing the Minister of Public Instruction; M. Thureau-Dangin, representing the Académie Française, and Dr. Roux, the Pasteur Institute. The speakers were M. Rufier, the late, and M. Renaud the present, Mayor of Dôle, M. Thureau-Dangin, Dr. Roux, and M. Mollard, a former member of the Chamber of Deputies. The latter compared Pasteur to Victor Hugo, "those two powerful brains united by mysterious affinities," which leads the *British Medical Journal* to remark that "surely there was never a more inept comparison. It would certainly require almost preternatural ingenuity to discover any affinity between the humble-minded seeker after truth, the patient investigator of facts, and the megalomaniac wordmonger, whom his own countryman Baudelaire described as '*un âne de genie.*' "

Marine-Hospital Surgeons Back from Cuba.—Dr. Gregorio M. Guitéras has been ordered from Matanzas to Philadelphia, and Dr. Arthur H. Glennan, for several years in charge of the service in Havana, has also been relieved and ordered to Washington.

The "Woman's Medical Journal."—At the recent annual meeting of the Iowa State Society of Medical Women this live and interesting journal was chosen as the official organ of the society. The July number was the "special Iowa number," and contained the address of the president, Dr. Margaret E. Colby, and other papers read before the society.

A Beaumont Memorial Lecture.—Dr. William Osler of Johns Hopkins University, Baltimore, will deliver a memorial address on "William Beaumont, the First and Greatest American Physiologist," at the Odeon, St. Louis, on Saturday, October 4, at 8 o'clock P.M. The address will be delivered under the auspices of the St. Louis Medical Society of Missouri.

Dr. Harold N. Moyer has been elected to the Chair of Neurology in the Chicago Eye, Ear, Nose, and Throat College. His work in the school will be on the lines of the "Clinical Aspect of Neurology in Ophthalmology."

Obituary Notes.—Dr. W. F. Hendrickson, instructor in Pathology in the University of Pennsylvania, died August 21 at the Union Protestant Infirmary, Baltimore, of meningitis. Dr. Hendrickson was born in Baltimore and was twenty-six years old. He was graduated at the Johns Hopkins University in 1896, taking high honors. Then he took up medicine in the medical school of the university, and obtained his degree in 1900. He went to the University of Pennsylvania soon afterward.

Dr. John Henry Longnecker, a retired physician, died on Tuesday in his home, in Islip, L. I., aged eighty years. He was a native of Lancaster, Pa., and was graduated from the Jefferson Medical College, Philadelphia. He practised his profession in Hudson, Mass., in New York, and later in Brooklyn. During the war he was assistant surgeon at Annapolis Hospital. For a time he was connected with a Pennsylvania regiment as surgeon.

Dr. William J. Larmer of this city was drowned in the North River on August 18. He had been ill and was recuperating in the country, but returned to the city a few days before his death. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1878.

The Rev. Dr. Thomas Gallaudet died at his home in this city on August 27 of cardiac trouble. He was born in Hartford on June 3, 1822, and was graduated from Trinity College in 1842. His life was devoted to the instruction of the deaf and dumb. His father, Dr. Thomas H. Gallaudet, founded the first permanent school for deaf mutes at Hartford in 1817, and this work the son continued. The latter also founded St. Ann's Church for Deaf Mutes in this city in 1851, and in 1872 he founded the Church Mission to Deaf Mutes. The founding of the Gallaudet Home for Aged and Infirm Deaf Mutes near Poughkeepsie was a later work of Dr. Gallaudet's. The mother of Dr. Gallaudet was a deaf mute, and he himself married a lady who was deaf and dumb.

Dr. Aaron Friedenwald of Baltimore died on August 26, aged sixty-five years. He underwent an operation for cancer a few days ago. He was a graduate of the University of Maryland School of Medicine in the class of 1860, and subsequently studied abroad. Since 1873 he had been a member of the faculty of the College of Physicians and Surgeons. He was a member of the Medical and Chirurgical faculty of Maryland, of which he was president. He was the first president of the Maryland Ophthalmological Society, and was a member of the American Medical Association. Dr. Friedenwald took an active interest in Jewish affairs, and held many offices in the various organizations. As a medical teacher he was widely known, and contributed frequently to the medical journals and proceedings of medical societies.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING—THE MANCHESTER MEETING—NATURE STUDY.

London, August 8, 1902.

The King looked in splendid health on his arrival in London on Wednesday in readiness for the ceremony of the coronation to-morrow. On Thursday morning a bulletin was issued to say he bore the journey without the least fatigue, had had a good night, and the wound was practically healed. To-day the King has issued a message to his people expressing heartfelt appreciation of their sympathy during his illness and deepest thanks to Divine Providence for preserving his life and giving him strength to fulfil his duties. It is understood that the message is written entirely and spontaneously by His Majesty. Another bulletin will be issued on Sunday, and that is to be the last of this historic series. The only object of this final announcement will be to assure the people that the King has not suffered from the fatigue and excitement incident to the coronation.

By a happy coincidence, the award of the King's prizes for essays in connection with his sanatorium is announced to-day—just on the eve of the coronation. You will remember that Sir E. Cassell's gift of £200,000 was devoted by the King to the establishment of a sanatorium for consumptives. Eight hundred pounds was apportioned to three prizes of £500, £200, and £100 for these essays. Competition was open to the whole world, and an architect could be associated with each author. No less than 180 essays were sent in, and the results are: First prize, Dr. Arthur Latham; Second prize, Dr. F. J. Wethered; Third prize, Dr. E. C. Morland. Four other essays are awarded honorable mention. They are by Dr. P. S. Hichens, Dr. Turban, Dr. Jane Walker, and Dr. J. P. Wills.

The Manchester meeting is over and the crowds who attended it have dispersed. Estimates of it by returned members vary a good deal—no doubt much influenced by the point of view. No one could get through the program of either the science or the amusement provided, so only scraps can be obtained through conversation, and they do not piece together properly. Your special reporters will have given you an account of much, though much must remain.

Some think it is almost an absurdity to divide into seventeen sections; others with narrower interests defend the scheme. To nearly all the set addresses appeal.

Mr. Walter Whitehead never fails to interest, and his address as President was looked forward to as a certain success and such it proved. His sketches of Manchester medical worthies, though of special interest on the spot, may be read anywhere with pleasure and prove a wholesome stimulus.

Mr. Whitehead is a great lover of art and a munificent patron. His liberality has made possible the issue of a volume commemorating the Manchester meeting, which has been written by Prof. Stirling and privately printed; but it may be hoped that it may be reproduced in a more accessible form. The book is entitled "Some Apostles of Physiology," and consists of brief biographies of the great masters of the science from Vesalius to Huxley. There are portraits of sixty-three of them in thirty-two plates, some of them photogravures and collotypes by Waterlows. Numerous engravings of prints and medallions are interspersed in the text. These have been obtained from various public and private collections.

The title of this magnificent work is, perhaps, scarcely exact enough for a scientific professor. The word "apostle" means someone sent, but these physiologists cannot be so described with accuracy. It is true the word has been loosely applied on many occasions, and perhaps the statement quoted by Mr. Whitehead in his address from Angus Smith that "Manchester was then the great center of sanitary knowledge and Percival the true apostle" may have influenced him and Prof. Stirling in the choice of their title.

The address in medicine this year may claim to be the most important scientific feature, for in all directions it is being praised and would increase Sir Thomas Barlow's reputation, if that were possible. The thesis which he said he endeavored "to drive home" is that advances in treatment are real only so far as they are harmonious with knowledge of the natural history of disease.

Professor Sinclair's address in obstetrics is also receiving unstinted praise for its straightforward criticisms and its appreciation of the importance of exact scientific clinical methods.

One member has called my attention to what he pronounces a "delightful sentence" in this address, viz., "Christendom, which now includes America." That little word "now" is very comprehensive. The professor also said he would not quote the learned German and speak of "a promised Land," but content himself with urging accurate clinical observation to see if the cause and remedy for cancer in women can be discovered.

For some years the National Temperance League has given a breakfast to the Association, and the "Temperance breakfast" has now become an interesting function and attracts a considerable number of acceptances.

This year Sir Victor Horsley presided and Professor Sims Woodhead was one of the speakers, so you may be sure the audience was larger than sometimes and very attentive. I hope those who also went to the annual dinner set a temperance example to the other *convives*, who, I am told, were convivial enough. So I hope they carried their example to the garden parties. A member tells me that for one of these the hospitable host laid in £200 worth of champagne, and when a friend, to whom he confided this fact, rather remonstrated with him, exclaimed "but I mean to do these doctors fine."

Our Manchester friends should remember the arsenical poisoning—a subject which again came up in the public health section when Dr. Reynold's pointed out that such poisoning was going on at least twenty years before it was discovered. Nor are spirits beyond suspicion. Wine may yet be indicted. At any rate, it is as well let alone in the afternoon—even by doctors on a scientific picnic.

We have been holding a "Nature Study" exhibition here, and last week, Professor Bickmore gave a brief account of the system of "visual instruction" carried on in your natural history museum. Mr. Choate introduced the professor as his distinguished friend and praised his work. Next day Professor Bickmore gave an address illustrated with lantern slides, on the Martinique disaster. The Ambassador and Professor were heartily thanked for their support in these conferences.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 21, 1902.

Polyhydramnios: Its Differential Diagnosis and Treatment.—Edward P. Davis reports five cases, and states that by polyhydramnios is meant more than two pints of amniotic liquid at full term. As much as seven gallons has been seen in the human species. The pathology of the condition is obscure. Any fetal condition causing venous engorgement tends to produce it. Irritating substances formed in lymphatics may cause it, and excessive secretion from the cerebrospinal canal of the fœtus may contribute to it. Polyhydramnios is normal at the fourth month, but its persistence is due to failure in normal development. Bacteriology gives no information on this subject, but cryoscopy may increase our knowledge by teaching us more regarding the osmotic properties of maternal and fetal blood and the liquor amnii. The diagnosis is made by first diagnosing pregnancy, then by observing that in polyhydramnios we can usually obtain evidence of faint uterine contraction, and can often insert the finger through the cervix and detect a presenting part. Ectopic gestation must be borne in mind, as polyhydramnios may complicate it. In ovarian cyst the illness is longer and the swelling at first unilateral. In ascites the dulness changes when the position of the patient is altered. While twin pregnancy can generally be recognized, it may sometimes be mistaken for polyhydramnios. In rare cases ovarian cyst complicating pregnancy may be difficult to diagnose and exploratory incision may be necessary. The treatment of this condition by drugs is useless. When the polyhydramnios is slight and the health of the patient good, pregnancy should not be interrupted. When distention increases rapidly and health is impaired, the membranes should be ruptured, and the fluid allowed to escape very gradually until the presenting part descends firmly against the cervix. Polyhydramnios is dangerous to the mother from over-distention, relaxation, hemorrhage, and increased liability to sepsis.

Journal of American Medical Association, August 23, 1902.

An Operation for Establishing a Cul-de-sac for the Wearing of an Artificial Eye; Report of Cases.—John E. Weeks says that all of the procedures heretofore devised have resulted in frequent failure. These failures result not from the sloughing of the transplanted flap, as even the heterogeneous flaps usually "take," but from subsequent shrinking, which results in complete loss of the primary favorable result. Heterogeneous flaps in the great majority of cases disappear almost entirely. He gives a description of the operation he has performed in five cases with unvarying success. One cul-de-sac only is restored at one operation, for the reason that if sloughing should occur the work of restoring one sac only would be destroyed; also because the time required to perform two operations would necessitate an excessively prolonged anæsthesia.

The Relative Indications for Enucleation and the Mules' Operation.—N. J. Hepburn states that enucleation may be performed for cosmetic purposes for wounds of the globe of considerable extent and for intraocular disease with destruction of vision and glaucoma absolutum. It must be performed in cases of sympathetic irritation, glaucoma absolutum with much thinning of the ciliary sclerotic in malignant growths of the eyeball and destructive ophthalmitis. The Mules' operation is adapted to cases where only a cosmetic result is required, where range of motility is desirable, in blind eyes without extensive ciliary involvement, and when it is desirable to prevent shrinkage of the orbital tissues. The main advantages of the operation seem to be the apparently increased rotation of the artificial eye, the greater plumpness given to the appearance of the upper lid, and the possible prevention of the filling up of the orbital pocket by connective tissue, which sometimes results in the final crowding out of the artificial eye.

Neuralgia of the Bladder.—G. Frank Lydston considers that, in the light of the newer pathology of diseases of the genitourinary apparatus, involving, as it does, mainly infection of the urinary way, the neuropathic elementin vesical disease is quite likely to be forgotten. It is, however, a very important point for consideration, because of (1) the relative importance of pain, *per se*, in diseases of the bladder; (2) the fact that very often no lesions are discoverable which explain the pain, or, at least, such lesions as are found appear too trivial to explain the severity of the pain experienced by the patient; (3) the tendency to too radical treatment in the endeavor to relieve pain, by compelling a cure of lesions which are so slight that topical applications are likely to do harm rather than good. Cystalgia may occur with lesions of the genitourinary apparatus, *i. e.* lesions affecting the urethra, bladder, kidneys, testis, and spermatic cord; with lesions of neighboring organs, such as the prostate, rectum, and anus. It may be incidental to ataxia or general paralysis, and be associated with gout, rheumatism, lead poisoning and malarial infection. There exists also an essential cystalgia. In the diagnosis the surgeon should be guided largely by the character and severity of any primary pathological condition that may be present, of an inflammatory or infectious character. He should also take into consideration the patient's general state. Care should be taken not to treat too radically lesions of the urinary way, the mildness of which is out of all proportion to the severity of the neuralgic manifestation. Narcotics, peros, hypodermically or per rectum; hot applications to the hypogastrium, instillations of very weak cocaine or menthol solutions into the deep urethra or vesical neck are generally useful, but the constitutional treatment is by far the most important.

Medical News, August 23, 1902.

The Symptomatology and Diagnosis of Acute Articular Rheumatism.—Leonard Weber believes that by the combined holding of the germ and nervous (*i. e.* trophoneurotic) theories he has generally been pretty well able to arrive at an understanding of the etiology of a given case. An acute attack generally comes on abruptly after exposure; the temperature rises quickly, the urine is scanty, highly colored, and in the majority of cases there are profuse acid sweats. Delirium is always present in the rarer cases in which there is hyperpyrex. The monarticular form of acute rheumatic arthritis is rare. The joint effusions are not often large, but pain and tenderness are almost always severe. Albuminuria is not uncommon, and endocarditis is of so frequent occurrence in acute rheumatism that we are justified in calling it one of its features rather than a complication. It is almost always "endocarditis verrucosa benigna" the ulcerative form being very rare, and concerns the mitral valve most frequently. The salicyl preparations are specific in their action for overcoming an attack, but they are not specifics in the sense of effecting a cure. The differential diagnosis has to be made from acute gonorrhœal arthritis, septic arthritis, the secondary multiple arthritis of acute infectious diseases, multiple neuritis, acute osteomyelitis and necrosis of bone, and multiple uric arthritis.

On the Pathogenesis of Acute Articular Rheumatism.—Heinrich Stern propounds a theory concerning the origin and nature of the rheumatic process, by the aid of which he attempts an explanation of (1) The hereditary transmission of the affection; (2) The proclivity to occur during a certain period of life; (3) The inclination to recurrence; (4) The abrupt onset; (5) The fluctuating pyrexia; (6) The synchronous and successive invasion of structures in different parts of the organism; (7) The self-limitedness. According to his theory, the rheumatic process is possible only on the basis of increased permeability of white fibrous tissue contained in the habitually-engaged parts of the motor apparatus, particularly in that of the serous and synovial membranes. The altered permeability, or a predisposition to the same, may antedate the rheumatic involvement, or it may be of synchronous or almost synchronous occurrence with the latter. The augmented permeability of this tissue is effected by the calcium salts of the blood which extract the cementing substance from the fibrous texture. Calcic bodies occurring in loose proteid combination in the blood are thrown out, deposited and temporarily retained in the articular tissues where their reactivity is displayed. The precipitation of the calcium salts from the circulating blood must be due to its altered composition, which latter may have arisen through any physical or metabolic disturbance. The increased permeability may permit the passage of such bodies which diffundate not at all, or with difficulty, only through the unaltered membrane. Among the permeating subtances we find fibrin, in which occurrence is dependent upon the presence of calcium salts. The hematic calcium salts aiding in the formation of fibrin very likely are identical with those which effect extraction of the cementing substance. The passage through the texture and into the synovial tubes, or their analogues, and the temporary retention therein, of abnormal quantities of fluid and salts and voluminous bodies like fibrin—practically a state of disturbed osmotic equilibrium for the time being—is speedily followed by all the usual manifestations of acute articular rheumatism.

New York Medical Journal, August 23, 1902.

Gastric Acidity.—L. H. Watson reviews the various attempts that have been made by physiological chemists to explain the chemical method by which the hydrochloric acid is separated from the serum by the gastric glands, and mentions the most frequent forms of gastric activity. In ulcer, neurasthenia gastrica, some forms of albuminuria, like interstitial nephritis, and in mitral stenosis and mitral insufficiency we often have hyperchlorhydria. In cholecystitis, cholelithiasis, cholangeitis, and hypertrophic cirrhosis of the liver, also, the acidity is usually high. It is especially in these cases of gall-bladder and liver troubles that he has found a high percentage of HCl. Of all forms of oversecretion gastrosuccorrhœa continua periodica, or Reichmann's disease is the most interesting.

Report of a Case of Successful Removal of a Kidney for Intermittent Hydronephrosis.—J. B. Boucher reports the case of a married woman, thirty-three years of age, who for thirteen years had attacks, at intervals, of from two weeks to two or three months, of severe pain in the right lumbar region, nausea and vomiting, with chilly sensations, followed by fever and restlessness. A tense tumor would suddenly develop, varying from the size of an orange to that of an adult's head; it extended into the abdomen to the right of the navel line, but its upper end was rather undefined, and could not be traced to the kidney. During the presence of the tumor the urine was frequently, though not always, diminished in quantity. A noticeable feature of the attacks was obstinate constipation. The affected kidney was removed extraperitoneally.

A Consultation with Professor Dieulafoy on Appendicitis.—Edmund L. Gros gives an account of the views held by Professor Dieulafoy on the treatment of appendicitis. Professor Dieulafoy believes in operating without delay in all cases in which there is high fever, a tendency to localized peritonitis and abscess. Appendicitis should no longer be considered as a local disease, but as an acute toxæmia. The canal through the appendix becomes obstructed by mucus, a foreign body, or fecal matter, and is thus converted into a closed cavity. The microbes imprisoned therein become highly virulent and secrete most powerful toxins. These germs may produce an ulceration, with perforation and localized or general peritonitis. The microbes may traverse the wall in the absence of any perforation, and thus start a contiguous inflammation. They may remain in the appendix and yet elaborate toxins so virulent that, if they are absorbed, they will poison the whole system. From the diagnostic point of view, Dieulafoy attaches great importance to the exact localization of the pain, to the hyperæsthesia of the abdominal wall over the appendix, and to the muscle spasm. Vomiting of blood in appendicitis is nearly always a forerunner of a fatal termination.

American Medicine, August 23, 1902.

Angina Pectoris.—Jay Perkins reports five cases of this disease, which he characterizes as one of the most interesting and fascinating to be found in the whole list of human ills. After a general discussion as to diagnosis, symptoms, differentiation, and so forth, he sums up the question of treatment as follows: The important thing in treatment is to search out the cause of the disease and the exciting causes of the attacks, and, so far as possible, to remove them. Of drugs, the one which seems to be of the greatest value is potassium iodide, given in moderate doses, not more than ten or fifteen grains, three times a day for a long time. During the attack, nitroglycerin is the best in many cases. Frequently, however, the only drug that will give relief is morphine, and sometimes a good deal of it is needed. The cause of the pain is not known, but it has been compared to that occurring in other hollow organs, as in renal and biliary colic; and it would seem that the same precautions should be used in the administration of morphine, for here and there the paroxysms may end suddenly, and then the poisonous symptoms due to the morphine will prevail, Therefore, if the pain is not controlled soon by morphine, chloroform or ether should be used.

Are Not Some Deaths During Operation in the Region Supplied by the Trifacial Nerve Due to Reflex Inhibition of Respiration and of the Heart?—William Harmar Good says it is a well-known fact that the peripheral sensory nerves all stand in a reflex relation to the cardio-inhibitory center, and also that the respiratory center is readily excited through reflex action, as instanced by the effect of cold water suddenly dashed upon the body, or by the accidental inhalation of strong ammonia. In etherizing rabbits it is noticed that as soon as the ether is applied to the nose the animal stops breathing for a more or less prolonged period. At the same time the heart is markedly inhibited; in fact, almost stopped. The recognition of these facts gave rise to the following questions: (1) is the inhibition due to the effect of the ether directly on the respiratory and cardio-inhibitory centers? (2) Is it due to irritation of the vagi endings in the lungs? (3) Is it due to irritation of trifacial fibers in the nasal mucosa, and if so, would other irritants act similarly? The writer answers these questions by pointing out that in the etherization of rabbits the reaction is so rapid as to preclude the possibility of the absorption and transmission of the ether through the blood of the medulla. Also that the application of ammonia or pinching the tip of the nose has the same effect. And further that from experiments on rabbits it can readily be proved that the respiratory and cardiac movements can be reflexly inhibited by irritation—either mechanical or chemical—of trifacial nerve endings. This raises the question whether during general anæsthesia in man, irritation of the trifacial nerve may not cause a reflex inhibition of respiration and of the heart, and death ensue? This result would occur most likely during partial or incomplete anæsthesia. After citing a few cases tending to prove the theory advanced, the author suggests methods of prevention and of overcoming the reflex after it has taken place. He points out that granting reflex inhibitions, it follows that the stape of primary anæsthesia is a dangerous time to perform any operation. It should not be commenced until anæsthesia is complete and the conjunctival reflex has been abolished. Moreover, the patient should not be allowed to come partially from under the influence of the anæsthetic during the operation. Finally, he emphasizes the treatment advanced theoretically by Ott and practically proved by Jackson. It consists simply of distension of the lungs by forced inspiration, by mouth-to-mouth insufflation, or even by means of the bellows, as is done in experimental work on animals.

Philadelphia Medical Journal, August 23, 1902.

Yellow Fever.—Frank H. Hancock gives a review of the contentions of those who have respectively advanced the claims of a specific agent of their own discovery, naming Freire, Carmona, Lacerda, Finlay, Gibier, Geverd, Sternberg, and Sanarelli. He also discusses the insecticidal methods of fumigation, and the passing of quarantine, citing figures to show that while general sanitation has lowered the mortality from tuberculosis, enteritis, and typhoid fever, it is not directly the agent in the stamping out of yellow fever, as infection and not condition has been responsible for this disease. As soon as its special mode of infection was demonstrated in 1899, Major Gorgas, with the ample authority of an autocratic government, proceeded with military exactness to execute the new ideas in the city of Havana. He divided the city into districts, organized a stegomyia brigade and an anopheles brigade, had houses inspected, wells made mosquito-proof, and the larvæ of mosquitos destroyed. The results were most effective. Yellow-fever cases began to diminish, and have ever since been under the control of those in charge. It is thus proved that there is no occasion for quarantine. The restraints upon commerce, the detention of ships with valuable cargoes and impatient passengers, seem to be at an end, so far as American ports are concerned, and in the nature of things it cannot be long before American methods will prevail in every yellow-fever center in the tropics, and this *bête noir* of humanity will be entirely stampedout.

Unusual Complications Supervening in a Simple Extirpation of a Multilocular Cyst of the Ovary.—Burdett Atkinson Terrett reports this case as one presenting several unique and interesting features, which he enumerates as follows: (1.) A multilocular cyst of the left ovary gave off a smaller pedunculated cyst, long enough to occupy the right inguinal region, which became sufficiently attached to the parietal peritoneum to hold it *in situ*, and thus simulate a second and entirely independent growth. (2) An abrupt rise of temperature occurred ten days after operation, and a pelvic abscess subsequently found without apparent cause, which abscess after evacuation resulted in the development of a urinary fistula, which closed spontaneously one week after discovery, the abscess itself becoming obliterated without apparent damage to adjacent structures. (3) An abscess developed later in the abdomen over the site of the cut omentum, which abscess formed a fecal fistula, which ultimately closed of itself, the abscess proper undergoing final obliteration. (4) The presence of streptococci in the pus of both abscesses demonstrated the common origin of the dual pus formation. (5) Two extra-abdominal incisions, one lumbar and one yaginal, became requisite, compelling a stay of over two months in bed, when every indication of an early and absolute recovery from the primary operation seemed assured. The writer concludes by saying that this patient is now in excellent health, having gained fifteen or twenty pounds, and resumed her household duties.

The Etiology and Diagnosis of Fractures in the Newborn.—W. Reynolds Wilson divides fractures in the newborn into those occurring before birth and those dependent upon delivery. Intrauterine fractures may be spontaneous or traumatic. In either case a pathological tendency in bony formation, coincident with faulty embryonic development, exists to a greater or less degree. Fractures occurring *sub partu* may be the result of a spontaneous process in delivery, or may be dependent upon obstetrical manipulation. He gives the common fractures of traumatic origin in the following order: (1) of the humerus; (2) of the clavicle; (3) of the femur. Fractures occurring at birth are usually the result—often inevitable—of the abnormal conditions present. Considering the question of diagnosis, the writer says that the first requisite in the study of these cases is the careful examination of the child after birth. The delivery may have been effected without force, the occurrence of fracture being therefore naturally overlooked, and yet the possibility of intrauterine fracture may determine the lesion irrespective of labor, or the fragility of the skeleton may predispose to fracture. In considering intrauterine fracture, the history of former deliveries, the course of pregnancy, and the condition of the mother must be taken into account. Tuberculosis and syphilis may be responsible. Two points are important in the study of such fractures: First, the fact that the lesions are generally multiple; second, the tendency to distinct loss in bony continuity. The writer concludes by saying that there are generally certain positive signs which should lead to diagnosis, such as a cry denoting pain, disability as to motion, dimpling of the overlying tissues, swelling of the soft parts, and undue mobility. Diagnosis by the radiograph is, of course, conclusive. The diagnosis may be obscured by the presence of fat in overgrown children.

The Lancet, August 16, 1902.

"Fourth Disease."—R. W. Marsden discusses the differential diagnosis of this disease, the definite existence of which, distinct from measles, scarlet fever, and rubella, was first advocated by Dr. Clement Dukes. From a consideration of the evidence upon which the differentiation of a "fourth disease" has been based, he is led to think that more conclusive details must be brought forward before we can feel satisfied that its definite nature has been distinguished. He does not deny, however, the possibility of its existence.

A Case of Nasal Vertigo Simulating Epilepsy.—Edward Woakes describes the case of a middle-aged man suffering from epileptiform seizures. Nasal examination showed enlargement of both middle turbinated bones; the left to a slight extent only, while the right presented a firm nodulated tumor, occupying the anterior ethmoid region of the nostril from its outer wall to the septum. It was removed with the author's cutting ring forceps; the sections showed expansion of the intertrabecular spaces, but no considerable cyst or cavity. For four and a half years the patient had no further attacks, but after the lapse of that time they recurred. The recrudescence of the symptoms was attributed to a morbid development of the left turbinal, which was found on examination. Ablation of the entire left middle turbinal bone, as well as the stump on the right side, brought about a definite cessation of the fits. The case may be regarded as an extreme type of a class of which there are many examples—that is to say, of vertigo of nasal origin. Though constituting a group of disease which is *sui generis* and quite distinct from epilepsy, it sometimes simulates one or other of the forms embraced by this latter term. It has, however, these advantages over true epilepsy, the existence of a recognizable *causa causans*, viz., ethmoidal disease and its almost certain cessation when this disease is radically dealt with.

A Case of Acute Mental Disorder, Probably Toxic in Origin, Secondary to Influenza: Result of the Necropsy Practically Negative, Except that the Bacillus Diphtheriæ Was Found in the Blood.—Alice N. V. Johnson and Edwin Goodall report the case of a middle-aged married woman, whose condition, clinically considered, was that of an confusional insanity. The necropsy negatived dementia paralytica and acute delirious mania. The patient appears to have been the subject of toxæmia, although the precise nature is obscure. The record of the mental disorder dates from a supposed attack of influenza, although it is rather remarkable that there should have been marked exacerbation of mental symptoms, without any recrudescence of the disease, from two to three months after their appearance. The negative result of the necropsy, beyond the slightly increased vascularity of the brain substance and some cardiac changes, was very remarkable. There was nothing in the respiratory tract to raise the suspicion of diphtheria, although certain parts were much congested. As regards the presence of the bacillus diphtheriæ in the blood, observers have pointed out that this is sometimes found in the organs (lung, liver, etc.) postmortem, and it is conjectured that the bacillus has, in such cases, passed into the blood stream after death. The patient may have had diphtheria, and this disease may have been the cause of her later mental symptoms. Microscopical examination of some sections from the parietal region of the brain showed that the tangential fibers and the superradiary were scanty and degenerate.

Remarks on the Life-History of Filaria Bancrofti and Filaria Immitis.—Louis W. Sambon, in a lengthy paper, takes exception to the statement of Dr. Giovanni Noè ("Remarks on the Life-cycle of Filaria Bancrofti, Cobbold, and Filaria Immitis, Leidy") that the mosquito propagation of filariasis has been discovered by Professor Grassi and the latter, and that Professor Grassi is entitled to claim the merit of having established a scientific basis for the prophylaxis of filaria Bancrofti. He also refutes Noè's assertion that Professor Grassi discovered the mosquito propagation of the malarial parasites of man, and that the researches of Major R. Ross on the transmission of the hæmamœba relicta did not preclude the propagation of the parasites by means of air and water. Touching Noè's reference to a visit which Dr. Manson and himself paid to Professor Grassi in 1900, he says that the purport of that visit is misrepresented both in Dr. Noè's paper and in the previous publication by Professor Grassi and Dr. Noè. Firstly, Dr. Nanson went to Rome to investigate on the possibility of carrying out a double experiment on the etiology and prophylaxis of malaria in the Roman Campagna; the experiment was successfully carried out by Sambon and Dr. G. C. Low in the following epidemic season. Secondly, Professor Grassi did not discover in Dr. Nanson's specimens a filaria at its maximum stage of development within the head section of a mosquito, and did not formulate thereat the hypothesis of the possible transmission of filariæ by means of mosquito-bites, for the reason that Dr. Nansen purposely brought his specimens from London to show Professor Grassi and others that filaria Bancrofti, after having reached a certain stage of development, migrated from the thoracic muscles of its intermediate host, most probably to reach the mouth parts of the insect, and to be inoculated into the human definitive host during puncture, as is the case with the malaria parasites.

The British Medical Journal, August 16, 1902.

Laparotomy Twice on the Same Patient within Eighteen Months for Different Varieties of Volvulus.—C. L. Williams reports this case as showing the tolerance of certain natives of India for severe operations, and their recuperative power. He operated on November 18, 1900, on a native woman, about fifty-three years old, and deaf and dumb, for an ordinary volvulus of the sigmoid flexure of three or four days' duration, and with enormous distention of the large gut, by incision below the umbilicus and untwisting of the gut. This was followed by an uneventful recovery. The same patient returned on March 19, 1902, with a twist of the mesentery from right to left through 180°, high up, and again with enormous distention of the small gut in the epigastrium, above the band formed by the twisted mesentery; this time the incision was made above the umbilicus, and the pedicle of the grape-like mass of small intestine with mesentery was untwisted; and again, after seventy-two hours' obstruction, the patient made an uneventful recovery.

The After-Treatment of Dislocation of the Shoulder. John A. Francis describes the method by which he treated three subcoracoid dislocations of the humerus. After reduction he bandaged lightly to give the joint one night's rest and the next day used passive movements, hand on opposite shoulder, arm over head and behind back, etc. Passive movements were continued for ten days, after which time gentle exercise for the arm was encouraged. The clothes were allowed to be put on the third day after reduction, care being taken only that the injured arm was the first in the sleeve and the last out in putting on and off the coat and greatcoat, with assistance from another person. A handkerchief sling was used for a week, and then the arm was allowed to hang loose. The patients all went to work at the end of six weeks, with a caution to be careful for a week or two in lifting weights, etc. At the present time, eight months after dislocation, they are all three engaged in hard work, with perfect shoulders, and no trace of want of power or limited action. The writer suggests that the long periods of inactivity recommended in many textbooks lead to flabbiness and degeneration in muscles and ligaments, which are likely to give rise to relaxation on resuming work. Massage also will not have so great an effect as voluntary effort in keeping the tissues in condition.

Plague as a Soil Infection.—In this paper Reginald Farrar disclaims any attempt to produce a novel theory of plague, but intends merely to summarize evidence available in the report of the Indian Plague Commission and other published documents, to the effect that outbreaks of bubonic plague are dependent on the infection with a specific microbe of soil contaminated with the excreta of rats or other animals that have suffered with the disease. This evidence further shows that, except in pneumonic cases, infection is ordinarily the result of direct inoculation from the soil, the element of personal communication being a factor of small importance He adduces as one most significant proof of this the fact that when the prompt evacuation of villages or infected areas is properly carried out the disease is completely arrested. The great susceptibility of the natives of India to plague lies largely in the fact that they are a barefooted race. To well-shod and well-clad Europeans plague is but slightly dangerous, the few cases that do occur being generally of the pneumonic type or the result of accidental inoculation, one of the few English children who died having contracted the disease from the bite of a plague-stricken squirrel. The writer ends by saying that if plague is to be excluded we must devote our energies not merely to the exclusion of plague-smitten persons and plague-infected articles, but especially to the exclusion of rats. To this end he warmly advocates the policy of rat-free ships.

Peripheral Neuritis of Tuberculous Origin.—This case is reported by J. Geddes Scott as being of interest from its unusual character. The patient on landing in Madeira after a three-weeks' voyage from London, *via* the Morocco Coast and the Canary Islands, complained of almost complete loss of power in both legs, which he first noticed on the second or third day of his journey. He was also suffering from extensive tuberculous disease of both lungs, although he considered himself practically cured of this trouble, and complained only of the condition of his legs. He showed every symptom of peripheral neuritis, being just able to stand on his feet, but quite unable to place one leg before the other. He complained of pain, especially in the calves, and numbness and tingling in the extremities; sensation was considerably altered, and there was much wasting of both limbs, especially the anterior tibial muscles, and both feet were markedly œdematous. There was no sign of neuritis elsewhere. He was put under a regimen of complete rest and tonic medicines, with massage and electricity to the affected limbs, but in spite of this, went rapidly down hill, developing profuse diarrhœa, probably due to tuberculous ulceration of the intestinal tract, and died of exhaustion a fortnight after coming under observation. The writer can see no cause for the neuritis except tubercle, as there were no spinal symptoms and alcohol was out of the question as a factor, as were all the other causes to which neuritis is commonly due.

Deutsche medicinische Wochenschrift, July 31, 1902.

A Symptom of Aneurysm Which Has Been Seldom Described.—Dorendorf calls attention to a symptom of aneurysm of the arch of the aorta which has hitherto received but little consideration. It consists in an obliteration of the left supraclavicular fossa. In many cases not only is the fossa obliterated, but a moderate-sized tumor takes its place. In all cases the left externa jugular vein is markedly congested and prominent. The deformity present in the supraclavicular fossæ may be temporarily made to disappear by pressure applied thereto from abode downward. In eight cases of aortic aneurysm recently examined this symptom was present in every instance, while it has never been observed by the author in other conditions. It is thought that the deformity is caused by the pressure of the aneurysm upon the left innominate vein.

Leucocytosis in Pregnancy, Labor, and the Puerperium.—W. Zangemeister and M. Wagner report the following observations: (1) The total leucocyte count in forty-seven non-pregnant women varied from 7,500 to 21,330. (2) A similar count in fifty-seven pregnant women gave practically the same figures. (3) Counts made upon sixty-three women during labor showed that in this condition a hyperleucocytosis was present, and that this reached its maximum about the time of the termination of the labor. The highest counts were approximately 30,000, and were obtained in those women who had shown the greatest number of leucocytes during pregnancy. (4) Counts made upon seventy-five women during the puerperium, show that, under normal conditions, the number of leucocytes rapidly diminishes after labor, so that there usual figures are reached within three or four days. In pathological puerperal conditions there seems to be no definite rule with respect to the degree of hyperleucocytosis present. A complicating mastitis, as a rule, gives high counts. Simple fetor is generally accompanied by low counts. In general, it may be said that the grade of the hyperleucocytosis during the puerperium corresponds with the amount of absorption taking place. In connection with these observations it is interesting to note that during labor, which is regarded as a physiological process, there occurs a hyperleucocytosis which is indistinguishable from that encountered in severe infectious conditions.

Berliner klinische Wochenschrift, August 4, 1902.

Fatty Degeneration.—P. Wulff reports a peculiar case of fatty degeneration of the tissues. The patient had just recovered from a severe attack of pneumonia when he was seized with symptoms of a perityphlitic nature. Upon operation the appendix was found to be sound, but above this and posteriorly there was found a large abscess, embedded in fatty tissue, a considerable portion of which was undergoing degeneration. This abscess was evacuated and packed with gauze. Several days thereafter profuse hemorrhage took place from the abscess cavity and death shortly supervened. Upon autopsy the abdominal fat was found to be greatly increased in amount, a large portion of which was undergoing a typical fatty necrosis. The chief location of this necrosis was the cæcal region. The chief interest of the case lies in the fact that the pancreas was found entirely normal and in no way involved in the fatty metamorphosis. It has been generally supposed that in fatty necrosis the primary seat of the lesion is invariably located in the pancreas, and that changes in this organ stand in a direct etiological relation to the disease. This case demonstrates, however, that such is not always the case, and that fatty necrosis may occur and the pancreas be in no way involved.

How Often in Appendicitis Is Typical Dulness in the Right Iliac Fossa Absent?—Riedel discusses the value of dulness in the right iliac fossa as a sign in the diagnosis and treatment of appendicitis. The decision of the question hinges upon the frequency of dulness and the time of its appearance in this condition. The experience of the author shows that in about 30 per cent. of all cases dulness is either entirely absent or can only be elicited late in the disease, when operative measures are of little or no avail. The chief reasons therefor are (1) The situation of the appendix; (2) The absence of infiltration. In no case is dulness elicited unless a sufficient amount of infiltration is present to give rise thereto. If the appendix is situated behind the cæcum, this amount is not produced until late in the attack, and dulness is, therefore, rarely available for either diagnostic or therapeutic indications. In the majority of instances in which the appendix is situated anteriorly the infiltration is sufficient to give rise to early dulness, but even here, when the appendix is deep-seated, this may not be the case. Because of these considerations, it is evident that he who relies on the absence of dulness in the right iliac fossa as a valuable sign in the diagnosis or treatment of appendicitis is on dangerous ground.

Hysteria Combined with Organic Lesions of the Nervous System Following Traumatism.—Ernst Meyer's patient was a male, forty-nine years of age, who, in December, 1900, suffered a slight traumatism of the left elbow. Shortly thereafter pronounced hysterical symptoms appeared. These consisted of paræsthesias, pains, weakness of the limbs, dyspeptic symptoms, and certain ill-defined psychical disturbances. After about four months there was added to these appearances tremors, muscular spasms, and disturbances of locomotion and speech. An examination at this time showed an absence of the patellar reflexes and a failure of the pupils to react to light. The disturbances of speech and psychical phenomena increased in severity, and the condition of the patient became markedly apathetic. Notwithstanding the development of these symptoms, denoting organic lesions of the nervous system, the hysterical appearances continued, especially the paræsthesias, which were intermittent and frequently changed their location. Throughout the entire course the intensity of the symptoms has been very varied, although there has been a steady progression toward the worse. It is evident from the symptom-complex that in this case there is present a true combination of hysterical symptoms and those dependent upon organic lesions of the nervous system. The latter are with difficulty definitely defined, but it seems most probable that they are tabic in nature.

Münchener medisciniche Wochenschrift, August 5, 1902.

Widal's Reaction in Weil's Disease.—L. Zupnik calls attention to Eckhardt's article in No. 27 of the *Münchener medicinische Wochenschrift* relative to a case of Weil's disease which gave a positive Widal reaction. Zupnik, nearly a year since, reported the following cases in which a positive Widal reaction was obtained: Four out of six cases of Weil's disease, two cases of cholelithiasis, one case of cholangitis suppurativa, and one case of carcinoma of the liver. While from these observations the typhoid origin of Weil's disease might be suspected, it is evident that such cannot be positively affirmed, since many cases of this disease fail at any time to give a positive Widal reaction

A Ruminating Family.—L, R. Muller reports the instances of a father and two sons, all three of which had been ruminates since birth. About fifteen or thirty minutes after a meal the regurgitation of the food began, and continued from one-half to one hour, according to the quantity of food eaten. As the food was regurgitated, it was remasticated and again swallowed. The two sons are in the best of health, and have never suffered with dyspeptic or other digestive disturbances. The father likewise always enjoyed good health until about six months previous to his death, when he developed symptoms of carcinoma of the stomach. The symptoms increased in severity, and before death occurred the patient became markedly cachectic. Upon autopsy an hourglass stomach was found, a carcinoma being located between the two portions. The cardiac portion and the œsophagus were greatly dilated.

Carcinoma of the Cervix as a Complication of Labor.—Bamberger's patient had passed without incident through six pregnancies. From the middle half of the present pregnancy there had been present periodical uterine hemorrhages, and the diagnosis of placenta prævia had been made. The author was first called to the patient after she had been five days in labor without having made any material progress. A vaginal examination showed that the cervix was about one-fourth dilated, very rigid, and eroded upon a considerable portion of its surface. Bimanual examination revealed the presence of a tumor about the size of a hen's egg, located on the left side of the cervix near its junction with the body of the uterus. The child being alive, the cervix was incised and extraction accomplished through podalic version. The infant was found to be in good condition and of normal proportions. The mother died on the second day under all the appearances of a septic peritonitis. The chief interest in the case attaches to the healthy condition of the child and its successful delivery.

Etiology of Eczema.—Heubel reports a case which adds still further evidence in support of the non-parasitic nature of eczema. The primary attack occurred when the patient was seven months of age and was being fed exclusively on the milk from one cow. All treatment was without avail. The source of the food supply was investigated, and it was found that the animal was being fed with an excessive amount of salt. This was ordered to be rectified. All treatment was discontinued. Shortly thereafter the cutaneous lesions began to improve, and in a short time healed entirely. In about three months a recurrence took place. Upon investigation it was found that the milk supply had been changed and was being obtained from another cow. It was ascertained that this animal, similarly as the first, was receiving an excessive amount of salt. The same course was pursued as with the first cow, and the eczema of the child promptly disappeared. It is interesting to note that another child, who was receiving milk from the second cow, was also suffering from eczema. Upon withdrawing the excessive amount of salt from the diet of the cow the eczematous lesions upon this child also healed. It cannot be doubted that in both of these cases the nutritive supply was the sole cause of the eczema.

French and Italian Journals.

The Functional Power of the Heart.—Giovanni Galli holds that the present classification of reduplication of the heart sounds into physiological and pathological is not correct, and that it would be better to classify them as diastolic reduplications of the first, second and third grade. Diastolic division is always pathological, that of the third grade being the gravest, and the least amenable to treatment by repose. The condition is an indication of cardiac insufficiency, and is therefore of value in determining the functional power of the heart. Left diastolic reduplication must be carefully distinguished from that of the right side. Rest is the best method of overcoming diastolic reduplication, and thus of treating cardiac insufficiency.—*Il Policlinico, July*, 1902.

The Peripheral Equilibrium Maintained in Motor Disturbances and Its Influence on the Functions of the Nerve Centers.—A. Codivilla concludes from his researches that operative measures performed on the peripheric organs with a view of restoring equilibrium of the force distributed to the articulations, acts not only by modifying the articular mechanism, but also by exerting an influence on the nerve centres. Just as the altered functions which rendered operation necessary have an injurious influence on the nerve centers, so does the restored functional power act beneficially. In cases of anomalous functioning of the motor nerve centers, restored peripheric equilibrium may overcome these disturbances. (1) The action of the injured center is eliminated, and normal action substituted. (2) From the abnormal centre certain conditions apt to cause grave disturbance are removed, such as those which tend to increase the tone of the nerve-cells and thus cause strong reflex excitation. (3) The nerve centre is enabled to profit by the educational effects of exercise.—*Archivio di Ortopedia*, 1902, *Part* 1.

A Case of Aortic Aneurysm.—Bourdillon reports this case. The aneurysmal tumor was formed by an irregular dilatation of the entire aortic arch, the diameter of which was about 20 cm. The aneurysm burst into the left bronchus, which was found at autopsy to be joined to the aneurysm and partly destroyed for a length of 5 cm. The life of the patient had been prolonged for two years by injections of gelatinized serum. The arch was lined with voluminous clots. They were adherent to the wall of the ascending arch. The descending branch was filled with a thrombus, which was easily detached from the arterial wall. This thrombus weighed 280 grams and formed an exact mould of the cavity. It was perforated by a cylindrical canal through which the blood flowed. By this arrangement the normal function of this part of the aorta was almost re-established, for although the vessel was so enormously dilated, the lumen for the blood current was only about 5 cm. in diameter.—*Revue Médicale de la Suisse Romande*, July 20, 1902.

Paludic Cirrhosis.—According to Géraudel, the cirrhosis of paludism has been distinguished especially by the coexistence of a great abundance of blood pigment, rather than of biliary pigment, in the interior of the hepatic cells. Connective tissue proliferation is found in all parts of the organ, even in the interior of the lobules. Paludic cirrhosis most often is distinguished by an insidious onset, a slow and progressive increase in volume of the spleen, which is always larger, comparatively, than the liver; anæmia more or less marked, the more or less early appearance of jaundice of a bronze hue, absence of fever, of pain, and of peritoneal reaction, a very slow course, and death from hepatic insufficiency. In the terminal stage all of the symptoms are exaggerated. The termination is not, however, always necessarily fatal. The prognosis varies with the stage. The treatment should consist in the administration of iodide of potassium, carefully given, in small doses, and in hydrotherapy.—*Gazette des Hôpitaux*, July 22, 1902.

Adrenalin in Metrorrhagia of the Menopause.—Debrand makes this report. One of his patients was a woman of fifty years, a neuroarthritic. Ergotin did not stop the metrorrhagia from which she suffered, and the writer gave her ten drops of a 1 to 1,000 solution of adrenalin. By evening the flow had diminished one-half. On the following day fifteen drops were administered. The improvement continued. On the next day twenty drops were given, and that day the hemorrhage ceased. The dose was then decreased in inverse gradation. Since that time several catamenial periods have occurred regularly. From all of his experience with this remedy, the writer believes that adrenalin is a hæmostatic of the first order in the severe metrorrhagia of the menopause, and very probably in other varieties of this affection. It would be of advantage to employ this drug at the onset of severe uterine hemorrhages. Unless the case is urgent, however, t would be better not to begin with a large dose.—*La Tribune Médicale*, July 23, 1902.

The Microbe of Epidemic Dysentery.—A. Chantemesse declares that the terms catarrhal, epidemic, and diphheritic dysentery have no definite significance. Catarrh of the large intestine is an anatomical lesion, which can occur in dysentery and in many other intestinal maladies. Geographical boundaries do not determine the etiological character of dysentery. A classification of the microorganisms which cause the disease is the only way to throw any light on this subject. In fact, the dysenteries, epidemic or sporadic, which appear in one region and another, are due to two microorganisms which are totally different, an amœba and a bacillus. The amœba of dysentery was observed by Kartulis in Egypt. Osler reported its presence in a liver abscess in a patient who had been attacked by dysentery in Panama. Amœbic dysentery develops in a manner rather sporadic than epidemic. It occurs most often in adults and most often in men. It may carry off the victim in a few weeks, but ordinarily its course is chronic. The stools contain mucus, blood, pus, and amœbæ. Periods of constipation and diarrhœa alternate. The disease may be cured or it may terminate in intestinal perforation or in abscess of the liver. The blood of such patients does not agglutinate the dysenteric bacillus (Osler). Bacillary dysentery is especially epidemic, infectious. It may cause death quickly or its course may be chronic. It gives rise to intestinal ulcerations. It sometimes occurs in isolated cases. It is due to a special bacillus, which is agglutinated by the blood of patients who have been suffering from dysentery for a number of days. The specificity of this microbe has been well proved. The bacillus multiplies in the intestinal cavities, in the walls of the large intestine, in the mesenteric ganglia, in the spleen, and often in other organs. The mortality caused by this bacillus is considerable.—*La Presse Médicale*, July 23, 1902.

Archives of Pediatrics, August, 1902.

Typhoid Fever Complicated with Pneumonia and Followed by Laryngeal Diphtheria.—Edwin Rosenthal reports a case in which the interesting point to note was that the diphtheria followed the typhoid fever instead of preceding it. Pleurisy and empyæma followed closely on the diphtheria, so that the child was constantly ill for a period of nearly three months. Three thousand units of antitoxin with calomel overcame the diphtheria. For the empyæma puncture and evacuation of pus had to be performed. The child is in a good condition, which gives hope of a final perfect health. The case shows conspicuously the recuperative powers of a child.

A Case of Chondrodystrophy Fœtalis.—John Lovett Morse reports the case of an infant of two months which belonged to a class of cases described variously as fetal rickets, osteogenesis imperfecta, achondroplasia, and chondrodystrophy fœtalis. In a general way, in these cases the trunk is normal, the extremities short and deformed, the head large, and the bridge of the nose flattened. Although many cases have been worked up macroscopically and microscopically, by competent observers, no scientific classification on pathological lines is at present possible. While the pathological lesions in the different specimens resemble each other in a general way no two cases show exactly the same changes. The author gives in detail the points which appear to be pretty well established. Chondrodystrophy affects not only the osseous system, but also the general nutrition of the fœtus, and is often associated with other malformations. Hence in most cases the fœtus dies in utero. Milder cases may reach adult life. But few cases have been reported in this country.

Norsk Magazin for Laegevidenskaben, August, 1902.

The Teachings of Experience in Regard to Labor Complicated by a Narrow Pelvis.—Dr. Dreyer has had an experience of 196 cases of narrowed pelvis in which he was obliged to intervene. He used the forceps 112 times; version and extraction were resorted to twenty-six times; pelvic presentation extracted eleven times. As between forceps and version, the author decidedly prefers the former. He is absolutely opposed to version as a prophylactic measure. Cæsarean section he performed once. Premature delivery was induced twenty-two times Out of all the 'cases 126 of the children lived. Five per cent. of the mothers died.

An Epidemic of Dysentery at Aeseral.—M. Geirsvold describes a small but severe epidemic of dysentery which occurred in a remote valley in Southern Norway in the spring of 1902. There were eleven patients with ten deaths. The well water was certainly at fault, for as soon as it was closed and only boiled water used the epidemic ceased. In all the fatal cases there was gangrene of the intestines. From the water, contaminated by human and animal dejecta, were isolated coliform bacilli, which produced a general hemorrhagic infection in animals, with special localization in the intestines, and a typhoid bacillus, non-virulent in animals. The Striga-Kruse bacillus was not found.

Medical Gymnastics and Massage in the Treatment of Heart Disease.—P. E. Giertsen holds that these measures are often of value, and to be used as follows: (1) Exercises addressed to the circulation, or else pétrissage of the muscles of the extremities and of the abdomen, to exert pressure on the veins, and drive the blood onward to the heart. (2) Respiratory exercises, increasing the capacity of the thorax and its aspiratory action on the larger veins, facilitating the evacuation of the network of capillaries, increasing the intake of oxygen and diminishing the venosity of the mass of the blood. (3) Mechanical treatment addressed to the cardiac region, tractions, vibrations, and frictions reducing the frequency of the pulse, as shown by the result of 6,000 observations made by Levin of Stockholm. (4) Judiciously chosen muscular exercises to increase the filling of the arteries and the evacuation of the veins. Patients may derive benefit from these procedures in the winter season, and in the summer carry out the mountain treatment as prescribed by Oertel. The two methods are not opposed, but admirably supplement each other.

A Peculiar Abdominal Tumor.—John Stephen M'Arale describes the case of a young woman, aged twenty-three years, suffering from an abdominal tumor. For over a year she had been in the habit of eating hay. She complained of morning sickness, vomiting after solid food, particularly meat, and occasional headaches. The tumor extended about 1½ inches below the umbilicus, was hard, and when fixed dull, on percussion. It was readily movable upward. The author operated, opening into the stomach midway between the lesser and greater curvatures, at the junction of the middle and pyloric thirds of the stomach. A sour-smelling fluid exuded. The tumor was grasped and excised and the tumor removed. Some pain and restlessness followed operation, but the patient made a good recovery. The mass of hay was in two parts, which were connected; the tail of the smaller tumor extended into the duodenum. The larger tumor, was over 1½ lbs in weight, and the pyloric one nearly ½ a lb. They measured 16½ inches in length and 3½ inches in breadth. The circumference at the largest point was 10 inches. The fibers of the mass were very strong, were not masticated, and, owing to their rigidity, the pyloris resisted their passage.—*The Dublin Journal of Medical Science.*

Some Work on a Curative Serum for Typhoid Fever.—William Royal Stokes and John S. Fulton have performed a series of experiments to test the effect of a serum of high immunizing power in cases of typhoid fever. They sum up the animal experiments as follows: The subcutaneous injection of the serum in doses of from $\frac{1}{600}$ to $\frac{1}{800}$ of the body weight will protect guinea-pigs against four times the minimum fatal dose of intraperitoneal injection with the typhoid bacillus. The injection of $\frac{1}{3000}$ to $\frac{1}{4000}$ of the serum by weight into the abdominal cavity will protect against five times the minimum fatal dose, and a dose of $\frac{1}{600}$ to $\frac{1}{800}$ of the body weight will protect against seven times the minimum fatal dose of the typhoid bacillus. At the present time only five cases of typhoid fever have received this serum treatment, and although the number is too small to to deduce any definite conclusions, the writers state that it is not difficult to produce a serum of high agglutinative strength and immunizing power by injecting the hog with pure typhoid cultures. The use of this serum appeared to give slightly favorable results in three of the cases. The writers will soon extend their observations in this field.—*Maryland Medical Journal.*

Book Reviews.

The Roentgen Rays in Medicine and Surgery. By Francis H. Williams, M.D. (Harv.), Graduate of the Massachusetts Institute of Technology; Visiting Physician at the Boston City Hospital; Fellow of the Massachusetts Medical Society, etc. Second edition. New York: The Macmillan Company, 1902.

That there is a widespread interest in all that pertains to the Röntgen rays, and especially their influence upon current medical thought, is shown by the rapidity with which editions of *x*-ray treatises are exhausted.

The present work is especially designed for medical men, and still the therapeutic application of the ray has been known for so short a period that the portion treating upon this most important feature is at the present day even inadequate to the requirements. Only forty pages have been added to the original edition, much of which is taken up with descriptions of apparatus, etc. Too little time between editions and lack of time for preparing the second account for a certain disappointment in the quantity and quality of alteration and addition.

The work is praiseworthy and most readable, but it is hoped that the next edition may be fully revised.

La Fototerapia. By Dr. Antonino Sciascia. Roma: Società Editrice Dante Alighieri, 1902.

This is a small brochure of 125 pages, presenting the clinical experience of the author since 1890 in the therapy of light. There are numerous illustrations of cases, including malignant pustule, tuberculosis, epithelioma, lupus, etc.

International Clinics, a Quarterly of Illustrated Clinical Lectures and especially prepared articles. By leading men of the medical profession throughout the world. Edited by Henry W. Cattell, A.M., M.D. Philadelphia: J. B. Lippincott Company, 1902.

The subjects included in the June number are all of an interesting character. Surgery of the Abdomen, including Hernia, is from the pen of Wm. B. Coley; Gynecology, by John G. Clark; Diseases of the Blood and Ductless Glands, the Hemorrhagic Diseases and Metabolic Diseases, by Alfred Stengel; Ophthalmology, by Edward Jackson.

There are only a limited number of illustrations, and the various topics discussed in the 440 large pages bring out much that is new and important. The work is one much better suited for occasional reference than for deliberate reading. Facts and figures are at times abundant, but this summer volume is not in the nature of light summer literature.

An interesting feature of this issue is the department of biographical sketches of eminent living physicians. Dr. Guy Hinsdale writes the eventful life of S. Weir Mitchell and John A. Wyeth. Both are illustrated. To close the usual number of articles and department work there is an essay on the Eightieth Birthday of Rudolph Virchow and one on the death of President McKinley.

The volume is well illustrated, having several colored plates. The "Clinics" can be said to be more than maintaining promises.

The Neuroses of the Genitourinary System in the Male, with Sterility and Impotence. By Dr. R. Ultzmann, Professor of Genitourinary Diseases in the University of Vienna. Translated by Gerdner W. Allen, M.D., Surgeon in the Genitourinary Department of the Boston Dispensary; Instructor in Genitourinary Surgery in Tuft's Medical School. Philadelphia: F. A. Davis Company, 1902.

This is the second edition of the Ultzmann translation, and the chief addition consists in the lengthened and improved article on forms of nervous impotence. Minor changes here and there bring the various chapters well up to date. With the exception of matters pertaining to sexual disorders, little has been added to the work as originally put out by the well-known Vienna teacher.

Though brief, the chapters as originally prepared cover the subject admirably.

The Practical Medicine Series of Year Books. Edited by Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. VII. Materia Medica and Therapeutics; Preventive Medicine; Climatology; Forensic Medicine. Edited by Geo. F. Butler, Ph.G., M.D., Henry B. Favill, A.B., M.D., Norman Bridge, A.M., M.D., Harold N. Moyer, M.D., Chicago: The Year Book Publishers, June, 1902.

The first portion of the seventh volume of this series deals with the recent advances in therapeutics and materia medica. The uses of light, liquid air, massage, electricity, etc., are all considered along with the latest knowledge of drugs. The section on preventive medicine is short but pithy, while climatology claims a more extensive recognition, and includes some interesting tables of various health resorts. The book, as a whole, is both interesting and instructive.

Charaka-Samhitâ. Translated into English by Avinash Chandra Kaviratna, editor of Chikitsa-Sammilani (medical journal in Bengali); practitioner of the Hindu system of medicine, etc. Calcutta: Kaviratna Press, 1902.

The twenty-eighth fasciculus of the translation of this classical Hindu treatise on medicine and hygiene, by Avinash Chandra Kaviratna, has reached us. In this part the chapter on management of the lying-in woman and training of the young child is concluded, and that on the "Life-breaths," as indicated by the complexion and the voice, is begun. This deals with prognosis, or rather with the signs of approaching dissolution, which seem to be many and diverse. It is most interesting to glance through this work and so to come in touch with the medical thought of ancient India, although we cannot quite share the enthusiasm of the learned translator or follow him in his belief in the practical value of the work in modern medicine. It must be confessed, however, that many of the hygienic saws of the illustrious son of Atri are surprisingly like some of the recently-promulgated dicta of latter-day sanitarians.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Volume V. January, 1902. Edited by Andrew J. McCosh, M.D., and W. Gilman Thompson, M.D.

The report is an elaborate publication of selected cases from the various services. Among others are the report of a case of tumor of the brain, localized in the right posterior central convolution, removed by operation and followed by recovery, by M. Allen Starr and A. J. McCosh; a series of cases of duodenal ulcer by Francis P. Kinnicutt; a report of three cases of acute pancreatitis, preceded by general considerations upon this subject, by George Woolsey; and a report of twenty-two cases of abscess of the brain, by John W. Coe and Burton J. Lee, including a table of differential diagnosis and of localization. The volume contains also two papers relating to ureter catheterization by F. Tilden Brown, in which are enumerated the disadvantages of the Kelly method of ureteral catheterization and also of the Harris instrument. The second part of this article is devoted largely to a description of the writers composite ureter cystoscope, by means of which instrument both ureters are catheterized at the same time.

Footprint Records.—Bettman describes a method of making permanent records of footprint impressions that is free from the inconveniences of that commonly in use This is usually some modification of Volkmann's method, and requires the coating of the paper with lampblack and the subsequent fixation of the imprint with varnish. Such paper cannot well be kept in stock, owing to the tendency of the coating to rub off, and its preparation before each time of using is both troublesome and untidy, through the soiling of the hands, which it is sure to involve. In addition, although the coarser features are shown, many finer details of marking and conformation entirely escape record. A material that is open to none of these objections is the ordinary sensitized paper of photographers. To use it for this purpose the sole of the foot is dampened with soda solution, such as is employed for fixing, and is then applied to the paper in the usual way for several seconds. A few moments exposure to sunlight brings out an imprint of beautiful clearness, in which the finest details are plainly visible. The paper is toned like an ordinary print, and is then ready for preservation as a permanent record. Many other chemicals beside the soda solution may be used to decompose the silver salt on the paper—for example, in hyperidrosis the perspiration alone will accomplish the result. The cheaper ferrocyanide blue print paper gives somewhat inferior but still very satisfactory results, the foot being moistened with weak acetic acid solution, and is especially to be recommended for the use of orthopedic shoemakers.—*Centralblatt für Chirurgie.*

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventieth Annual Meeting, Held at Manchester July 29, 30' 31, *and August* 1, 1902

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 314)

SECTION OF OBSTETRICS AND GYNECOLOGY.

Wednesday, July 30—*First Day.*

The Manchester School of Obstetrics and Gynecology. The President, Dr. LLOYD ROBERTS of Manchester, delivered an introductory address with this title:

The founder of the school was Charles White, born in Manchester on October 4, 1728. His father, Thomas White, also a doctor in Manchester, was the first to perform the cæsarian section in the neighborhood. Charles White was a fellow-pupil of John Hunter, and with him attended the lectures of Dr. William Hunter, and remained the friend of both through life. He was Surgeon to the Royal Infirmary for thirty-eight years, an institution he aided in founding, and to the Manchester and Salford Lying-in Hospital for twenty-one, in the foundation of which he also took part; he was the first man midwife extraordinary appointed to the hospital. He died in the eighty-sixth year of his age, on February 20, 1813. In the early part of the eighteenth century midwifery was not practised to the same extent by men as it is at the present time, and the treatment of lying-in women was crude and unsanitary. After labor women were kept in rooms heated to excess, the windows and doors being closed and covered with curtains, so as to prevent as far as possible the access of fresh air. White had the courage to revolutionize this most objectionable usage; he opened the closed windows and doors of the lying-in room and nailed them open. The consequence was that the most prevalent complications of labor—miliary fever and puerperal fever—became much less common. In 1784 White published a treatise on the nature and cause of the swelling in one or both legs, which sometimes happens in lying-in women; this was probably the first book on the subject written in England. Among other important advances in treatment advocated by White were: not tying the navel string before cessation of the circulation; removal of the placenta and the membranes by manual extraction, aided by pressure on the fundus; the recognition of the possible septicity of the lochia with the recommendation to inject antiseptic solutions into the uterus. The marvellous manner in which, by well nigh a century, he anticipated the doctrine of septicity and its prevention is clearly shown in the following quotation: "I must not omit to mention the good effects I have experienced from emollient and antiseptic injections into the uterus by means of a large ivory syringe, or an elastic vegetable bottle. In those cases where the lochia have become acrid and putrid, and by being absorbed into the circulation have served as a constant fomes to the disease, I have by this means known the fever much assuaged and in many cases wholly extinguished; for though, as I have before observed, the quantity of the lochia is not to much regarded, the quality of this discharge is a matter of infinite importance."

Next in eminence to Charles White was a contemporary and friend of his, John Hull, the son of a surgeon, born on September 30, 1761. In 1794 he went to Leyden and obtained the degree of Doctor of Medicine. Two years later he removed to Manchester, where he practised until 1838. He died at his native village of Poulton-le-Fylde in 1843, aged eighty-two years. In 1800 Hull published an essay on phlegmasia dolens, including an account of puerperal peritonitis. In 1801 he translated and published two memoirs on cæsarean section by M. Baudelocque, sen. In 1798 he wrote a defense of cæsarean section in the form of a letter answering some criticism indulged in by Simmons, one of his contemporaries, in relation to a case that had been operated on by Hull

At the time when White and Hull were about at the end of their careers came Kinder Wood, who was born in Oldham in 1785, died December 30, 1830, in Manchester, aged forty-five years. In 1826 he was appointed lecturer on midwifery at the Pine Street School of Medicine, being the first lecturer on this subject in the first complete school of medicine in the provinces. In 1822 Wood was the first to advise, in certain severe cases of placenta prævia, the entire detachment of the placenta from the os and cervix uteri, and then that the rest should be left to nature.

Also contemporary with Hull and Kinder Wood was Thomas Radford, a man of strong character, great individuality, and much ability. His name is perpetuated in the Radford Library, which he founded. He was born on November 2, 1793, and died on May 29, 1881, aged eighty-seven years. He was elected on the staff of the Lying-in Hospital in 1818. In 1854 he delivered the first address ever given on obstetrics before this association. Radford was one of the first in England to advise abdominal section for the removal of diseased ovaries, and he gave much assistance to Charles Clay in his early ovariotomies.

The next in order was John Roberton, a Scotchman, who was born in 1797 and died in 1876. He was surgeon to the Lying-in Hospital and lecturer on midwifery at the Marsden Street School of Medicine. He invented a pair of long forceps which has been the model of many instruments of this class. The forceps called after his name are still used in this neighborhood.

Charles Clay was born at Bredbury, near Stockport, on December 27, 1801, and died at Poulton-le-Fylde on September 19, 1893. He studied in Edinburgh and at the Manchester Royal Infirmary, and he settled in Manchester in 1839, in which year he performed his first ovariotomy and removed an ovarian tumor weighing thirty-six pounds; it is said that the operation occupied only ten minutes. In 1865 he published an account of 111 cases of ovariotomy, seventy-seven successful, and in 1880 his cases amounted to 395 operations with only 101 deaths. In 1845 he removed the whole uterus for fibrous tumor; this was nearly twenty-five years before Koeberlé's case. He was one of the first to advise the long incision, and in 1843 was the first to employ drainage in ovariotomy. He brought into use the term ovariotomy, which was suggested to him by Sir James Simpson. Clay was, indeed, the father of ovariotomy as far as Europe is concerned. Peaslee, in his work on ovarian tumors, says that to Charles Clay of Manchester, more than to all other operators, the credit belongs of having placed the operation of ovariotomy on a sure foundation. Johann Martin Fehr of Heidelberg calls him the original hero of the operation.

A contemporary of Clay was William James Wilson, born in Leeds, died July 19, 1855, who was elected man-midwife in ordinary to the Manchester Lying-in Hospital in 1813. He was the operator in a case of cæsarean section on May 24, 1821. He was also an oculist of great distinction. Among others he operated for cataract on the father of Charlotte Brontë, who came to Manchester for that purpose.

James Whitehead was born in 1812, and died in Manchester in 1885. His father was a herbalist and a dealer in simples. He became a pupil of Mr. Clough, a surgeon of the Manchester Lying-in Hospital, and in his turn he also was elected surgeon to the same hospital. He was a man of great energy, industry, and endurance. His interest was centered on the medical side of the diseases of women and children. In 1847 Whitehead published his work on the causes and treatment of abortion and sterility. He also published in 1851 another work on the transmission from parent to offspring of some forms of disease and of morbid taints and tendencies.

Edward Stephens was born in Manchester in 1804, and died September 14, 1863. He was for many years surgeon and consulting surgeon to St. Mary's Hospital. He was most dextrous in the use of the forceps and in all midwifery operations; he had an extensive knowledge of gynæcology, especially of the diagnosis of abdominal and pelvic tumors..

John Thorburn was born in 1834 at Huddersfield and died at Manchester in 1885. In 1866 he took part in the foundation of the Southern Hospital for Women and Children. In 1873 he was appointed obstetric physician to the Manchester Royal Infirmary, and was the first occupant of the post. When the Medical School, at which he was lecturer, was incorporated with Owens College, he became the first professor of obstetrics and gynecology. He contributed among other papers one on the treatment of the unborn child. He had just finished his most impotant contribution to the literature of his subject—a practical treatise on the diseases of women—when death called him away.

Dr. Curatulo of Rome, in proposing a vote of thanks, said that his countryman, Scipio Mercurius, mentioned in the address, was the inventor of the position known as Walcher's position.

The Modern Indications for Cæsarean Section.—Dr. Galabin, obstetric physician to Guy's Hospital, London, opened the discussion on this topic. He said that cæsarean section was most often required in cases of contracted pelvis, though bad cases of contraction were not common in England compared with some continental countries. The mortality of one of the latest tables published was 3 per cent., but this was an ideal mortality when all the circumstances were favorable. Another table of 279 cases gave 5.1 per cent. mortality. Dr. R. P. Harris of Philadelphia in 1894 recorded the mortality of the operations performed in Great Britain up to that date as 31 per cent. The mortality of embryotomy was, he thought, generally put too low. In Guy's Hospital the mortality of embryotomy in severe contraction of the pelvis was less than in the moderate degrees, because, in the former, time had not been lost in futile attempts at delivery. Charles reported the following mortality: Ninety cases of embryotomy, mortality 6 six per cent.; eleven cases of cæsarean section, one death; fifteen symphyseotomies, one death; 100 cases of induction of premature labor, no maternal death, fetal mortality, 36 per cent. He would conclude that the mortality of embryotomy was not less than 6 per cent. The conclusion was that cæsarean section should be the operation of election when (1) The decision could be made before the onset of labor; (2) Septic surroundings were absent; (3) The operator was versed in abdominal surgery.

Embryotomy would still have to be done in a large proportion of cases where (1) The patient had been long in labor, and (2) The surroundings were bad; and he did not think that embryotomy could ever be abolished under these conditions. As to the question of cæsarean section, after trying forceps in prolonged labor, personally, if an attempt had been made to deliver through the pelvis, he chose embryotomy; but where the labor had been prolonged only, without attempts at delivery, he would choose a cæsarean section in private practice. Unless the operator was skilled in abdominal section, it was better to do embryotomy.

In the highest degrees of contraction, with a conjugate of two and a half inches or less, craniotomy was advisable in *all* cases, because if the contraction was diagnosed as it should be, and measurements taken, no attempt at delivery per *vias naturales* ought to be made. He did not advise sterilization, because cæsarean section might be repeated on the same subject, but if sterilization were decided on, he would perform hysterectomy. In obstruction of labor by ovarian cyst cæsarean section had been proposed, but a better plan was to do vaginal ovariotomy.

The name of Porro's operation should be reserved exclusively for cases in which the pedicle was treated by the extraperitoneal method. In cases of labor obstructed by cancer of the cervix, cæsarean section was called for, but the results were bad, owing to the septic conditions prevailing.

Symphyseotomy was not in much favor in this country. Pinard's statistics showed a mortality of 12 per cent. The objections to the operation were: (1) The dangers of lameness and bladder troubles afterward, and (2) The fact that one could not sterilize the patient. The only cases in which symphyseotomy should be done were those in which the contraction was slight and forceps had failed to deliver.

The mortality of induction of labor was not more than 1 per cent. The frequency of craniotomy in Guy's Hospital Charity had been one in one thousand. The frequency of cæsarean section may be increased at the expense of the induction of premature labor, but he did not think that the latter operation should be given up as some had advised. The speaker thought cæsarian section should be decided on in cases where induction of labor had not succeeded in saving the child on a previous occasion. In a few cases cæsarean section had been done for placenta prævia; the mortality of six such cases had been given as 17 per cent. The operation had also been done for cases of concealed accidental hemorrhage with an undilated os. A doubtful extension of the operation had been to cases of puerperal eclampsia, and the mortality of recorded cases was 60 per cent. In Guy's Hospital Charity eclampsia treated by other methods had yielded a mortality of 9 per cent.

As regards the ethical question, he asked, could a doctor throw up a case, after undertaking it, if the patient refused to submit to cæsarean section on his advice? and his reply was decidedly "no."

Dr. Murdoch Cameron of Glasgow read a paper entitled, "Remarks on Fifty Cæsarean Sections." The cases were all of pelvic contraction; the conjugate in no case had been above two and three-fourth inches. Many had undergone craniotomy several times. Statistics were untrustworthy, because no comparison could be drawn between cases seen early and those which had been a long time in labor and in which many attempts at extraction had been made.

The operation was one of election when the child was alive and the operation could be performed at the onset of labor, before rupture of the membranes, and by an experienced operator. The speaker would never do it for placenta prævia, though he might for eclampsia. He ligated and divided the tubes in every case. His statistics showed the following results, the cases being divided into three groups: (1) Twenty-one cases, three deaths; (2) sixteen cases, seven deaths; (3) Thirteen cases, no deaths; Total, fifty cases, with ten deaths.

Dr. Munro Kerr of Glasgow read a paper entitled, "Some Experiences of Fritsch's Fundal Incision in Cæsarean Section." He said that it was of the greatest importance not to injure the lower uterine segment. The points about Fritsch's incision, which was a transverse incision of the fundus, were: The abdominal incision could be made higher up; the placenta was more frequently encountered, but he had found that, whatever the incision, the placenta was encountered in 50 per cent. of cases; the bleeding was said to be less, but he considered this doubtful; the uterine wound was said to be smaller afterward, and he had found this to be the case; it was said that the child would be more readily extracted, and with this he agreed.

The only serious objection which he had found to this incision was that the uterus became adherent higher up on the abdominal wall than in the older incision, and this interfered with involution.

Dr. Jardine of Glasgow, in continuing the discussion opened by Dr. Galabin, said that cæsarean section had been performed more frequently in Glasgow than in any other town in Great Britian. He did not think cæsarian section for eclampsia was to be recommended; he had performed it in one case in which the eclampsia was associated with contracted pelvis. He entirely agreed that it should never be done for placenta prævia. He had made up his mind that he would do cæsarean section in the first case of accidental hemorrhage with undilated os that he encountered, because his mortality from such cases treated in the usual way had been very heavy.

Professor Spencer of University College, London, was pleased to see that Dr. Galabin refused to recognize an impacted ovarian tumor obstructing labor as an indication for cæsarian section. He would not sterilize the patient when he performed cæserian section and did not consider it his duty to do so. One indication for cæsarian section which had not been mentioned was the presence of scars in the vagina obstructing delivery. He did not believe in the fundal incision, as he considered it more likely to lead to intestinal adhesions; in the usual anterior incision the scar adhered to the abdominal wall.

Dr Haultain of Edinburgh said that the doubtful case were those having a conjugate of three inches and upward. Ought one to recommend cæsarian section in these cases in which craniotomy was absolutely safe, while cæsarian section was fraught with danger and had a mortality of at least 10 per cent.?

Dr. Walter of Manchester drew attention to the fact that though the immediate fœtal mortality of induction of labor was given as 30 per cent., many more children died within the first few years of life.

Dr. Galabin, in reply, agreed with what had been said as to the greater liability to intestinal adhesions if the fundal incision were adopted. He agreed that the mortality of cæsarean section was greater than both craniotomy and induction of labor, though he had not found any statistics of embryotomy showing a mortality lower than 6 per cent. As regarded the ethical question of sterilization he thought if the woman refused to have the operation performed unless she were at the same time sterilized then he considered we were quite justified in carrying out sterilization.

Total Abdominal Hysterectomy, Especially by Doyen's Method, for Fibromyoma Uteri, with Notes of Fourteen Cases.—Dr. Herbert R. Spencer of London read this paper He held that the presence of fibroids was not in itself an indication for operation. Cystic fibroids, large fibroids in young subjects, and fibroid uteri suspected of malignant disease should be removed even when no symptoms were present. In other cases operation should be done only when serious symptoms were present or threatened. He called attention to the dangers of mistaking sarcoma and cancer for fibromyoma. Enucleation, especially through the cervix, was the best operation in suitable cases. Normal pregnancy and labor might follow it. Vaginal hysterectomy was to be preferred to abdominal for tumors not larger than a fœtal head.

The three chief methods of abdominal hysterectomy were as follows: (1) Supravaginal amputation with extraperitoneal treatment of the pedicle. Mortality slight. Disadvantages: Prolonged convalescence and risk of hernia. (2) Supravaginal amputation with intraperitoneal treatment of the pedicle. Disadvantages: Drainage not good; danger of hemorrhage; infecton and sloughing of cervix; leucorrhœa; infection of stitches; adhesion of intestine to stump; the growth may be sarcoma or cancer; malignant disease may develop in the cervix. (3) Total abdominal hysterectomy. Supposed disadvantages: Operation long; danger of injuring ureters; danger of vaginal hernia. Only the first objection is a real one if Doyen's method be employed. The average duration of the fourteen operations was 87 minutes.

In conclusion he said that total abdominal hysterectomy was superior to supravaginal amputation, and Doyen's method of performing it was the best. This method was employed in twelve out of the fourteen cases reported by the author of the paper.

Thursday, July 31—Second Day

Phototherapy in Obstetrics and the Diseases of Women. Professor Curatulo of Rome read this paper. He used the electric incandescent light, which gave out three kinds of rays: heat rays, light rays, and actinic or chemical rays His specially-devised speculum enabled light to be divided and use made of each kind of rays separately It was made of glass, shaped to the vagina, with a beveled upper extremity; it had double walls, with a space between, through which it was possible to circulate a current of cold water. The uterine end of the speculum was pressed against the cervix to secure anæmia of the mucous membrane, which was an essential condition of the treatment. If the space between the two walls was filled with a solution of alum the heat rays would be absorbed; if filled with a solution of copper sulphate, the chemical rays only were allowed to pass; and a solution of cochineal or other red die allowed the passage of the heat rays only. He made use of this mode of treatment in metritis and hypertrophy to promote the absorption of exudations, for ill-developed uterus, and for sterility.

Dr. Walter of Manchester asked how many applications were required.

Mr. Targett of London had seen good results from light treatment of cases of epithelioma of the skin and thought it probable that in some cases of slowly-growing epithelioma of the cervix in old women it might be of advantage.

Professor Curatulo, in reply, said that in cases of chronic exudation he had obtained good results from forty to fifty applications repeated every other day and each lasting half an hour.

Etiology, Diagnosis, and Treatment of Ectopic Gestation.—Dr. G. T. Harrison of New York read a paper with this title. He said that he would restrict his remarks to cases of tubal gestation in the early months. It might be held that the possibility of ovarian gestation was now proved. A wrong belief was still cherished that tubal gestation usually ended in rupture, but he considered that in most cases the ovum died very early, before rupture occurred, and before attempts at tubal abortion with subsequent absorption took place. He would place the frequency of this latter occurrence as compared with rupture of the tube as about eight to one.

As regarded *etiology*, some of the factors were previous conditions of the tube. (1) Congenital—persistence of the fœtal form; (2) Acquired—salpyngitis. Recent investigations had made it a doubtful matter whether an actual decidua formed.

As to the question of *diagnosis*, the physician was not often consulted till after the ovum had died. Before death of the fœtus the usual signs were amenorrhea, enlargement of the uterus, and the presence of a soft elastic tumor in the tube (the latter was only simulated by hæmato- and pyosalpynx. A transitory hardening of the tubal tumors had been made out. The signs of death of the ovum were a mass in the pelvis and a discharge of tarry blood. Vesical tenesmus was common. The diagnosis of interstitial pregnancy was very difficult. Hæmatocele was recognized by the crowding forward of the uterus and the mass in the pouch of Douglas though the mass was occasionally in front or at one side. Rupture of the tube could easily be diagnosed.

Treatment.—As soon as pregnancy in the tube was recognized the ovum should be removed at once. The speaker preferred the abdominal route. It was necessary to secure all bleeding vessels at once, and this was best done by the abdominal route. The uterus was used as the landmark after opening the abdomen. If the patient were bloodless, he would precede operation by subcutaneous saline infusion, give camphor in olive oil subcutaneously, and give ether in preference to chloroform. If a hæmatocele had already formed one might wait for absorption. Pelvic hæmatocele meant extrauterine gestation and usually tubal abortion. The question of operation in these cases was very difficult, but he would say that when the hæmatocele was enlarging and the patient's health deteriorating an operation was called for. The supervention of symptoms of putrefaction indicated operation, and in that case posterior colpotomy could be done.

Professor Spencer of London said that it ought to be known that the majority of cases of tubal gestation did not rupture, but when rupture occurred operation was urgently required. Cases of tubal abortion with hæmatocele seldom terminated fatally, even if not operated on. He preferred the abdominal route.

Professor Byers of Belfast did not believe that antecedent disease of the tube was a necessary factor in the etiology of the disease. The greatest advance lately had been the use of saline injections and strychnine in cases of severe collapse; in such cases he often used local anæsthesia.

Dr. Donald of Manchester pointed out there was often no clear history of a missed period. The treatment when the pregnancy was still developing was operation, but when there was evidence that the fœtus was dead we might wait and watch the effect of rest in bed. He considered the abdominal route the best in all cases except those of rectouterine hematocele.

Dr. Walter of Manchester said that we ought to diagnose between rupture of the tube and abortion, the severity of the symptoms would assist the diagnosis. The discharge was often dark brown rather than frankly hemorrhagic.

Mr Targett of London had seen two cases of tuberculous disease of the tube associated with extrauterine gestation. He had seen the entire tumor lying in front of the uterus.

Dr. Hellier of Leeds used large doses of strychnine, 10 minims of the official solution repeated several times. He preferred intravenous injection to intracellular.

Dr. Harrison, in reply, said, in reference to diagnosis previous to rupture that no other tumor presents the same elastic, soft feeling except hæmatosalpynx or pyosalpynx, and the history would exclude these.

As regarded the question of operation in hæmatocele, where there was any sign of recrudescence of the hæmatocele or the general health was suffering he would operate.

The Use of Potassium Chlorate in Habitual Death of the Fœtus in the Later Months of Pregnancy.—Dr. Jardine of Glasgow read a paper on this subject He said the late Professor Simpson had proposed this remedy under the impression that by it oxygen was given to the fœtus, this was probably not true, but he himself considered that it had a good effect on the uterus. No ill effects to the mother had followed in any of his cases; the dose was fifteen grains three times daily after food. He narrated five cases.

Intermenstrual Pain Cured by Two Successive Oophorectomies.—Dr. Whitelock of Oxford reported this case. The patient was a schoolmistress. The pain, which rendered her unable to work, began ten days before the period and completely disappeared twenty-four hours before the flow commenced. The cervix was dilated, but no relief followed. The left ovary, which was enlarged but not prolapsed, was removed by abdominal section At the operation the right ovary was seen to be cystic, but small; the cysts were punctured. Pain returned and another abdominal section was done eighteen months later. At this time the right ovary was the size of a small orange and the uterus was seen to be enlarged by a small fibroid. The right appendages were removed. The patient was now quite well. The speaker thought that the fibroid had more to do with the pain than the ovarian condition.

So-called Neurasthenia, Hysteria, and Abdominal Section.—Dr. Stuart Nairne of Glasgow read a paper with this title. In these cases abdominal section showed very diverse conditions, in many cases of most persistent abdominal vesicocele, in which he had opened the abdomen, he had found a condition which he described as rigid uterus, and he attached much importance to this condition.

Friday, August 1.—Third Day.

The Operative Treatment of Prolapsus Uteri.—Dr. Berry Hart of Edinburgh opened the discussion on this topic. He said that the apathy which existed on this subject was due partly to general ignorance of the anatomy of the condition and partly to the disheartening effects of recurrence after operation which was frequent.

The relations of parts in an advanced prolapse, as shown by frozen sagitto-mesial section, proved that it was not a mere uterine displacement, but a descent of the whole pelvic floor. The bladder and the vagina were driven down, and these, with part of the broad ligament, lay below the conjugate diameter of the outlet of the pelvis. We had no knowledge of the side relationships in this condition, but the speaker believed that the construction of the pelvic connective tissue with the obturator internus and lateral wall of the pelvis was greatly stretched. He had found the uterine artery and the ureter not displaced at the outer side, but markedly displaced inside of the point at which they crossed one another. There was no separation between the fascia and the broad ligament, but the triangular ligament was greatly stretched. There was an actual hernia sac lined internally by peritoneum, and having for coverings the bladder and the vaginal wall, and its canal being bounded behind by the sacrum and in front by the pelvis. In the normal position of parts the bladder lay behind the pubes, the posterior vaginal wall lying on the anterior pertal wall, and a strong fascial band tying the vagina to the fascia. The supporting parts of the pelvic floor were the perineal muscles and the levator ani.

Among the causes of this condition were great intra-abdominal pressure; perineal tears; looseness of parts from stretching during parturition. The speaker attached litttle importance to backward displacement of the uterine as a factor in prolapse.

In the diagnosis from hypertrophy of the cervix, it should be remembered that in this condition the fornices remained at their normal level. When the patient was told to strain in cases of prolapse the parts appeared in a definite order—firstly, anterior vaginal wall from below up, then cervix, and lastly, the posterior vaginal wall from above down.

One could operate on the prolapsed part or on the supporting part, but only the lower portion of the latter was accessible to operation, and this rendered such operations unsatisfactory. The best operations in the category were amputation of the cervix, anterior and posterior elytrorrhaphy, and perineorrhaphy.

The cervix was amputated by a circular incision of the mucous membrane, the latter being stripped up and used to cover the stump after amputation. The cervix was split laterally and each lip divided and the mucous membrane sutured over. Anterior elytrorraphy was done by removing a large oval surface of mucous membrane, this was clipped off with scissors and the new edges united by catgut ligatures.

The speaker performed the perineorrhaphy by Bischoff's method of removing the tissue, and Emmett's method of applying the sutures. Some preferred an operation on the lateral walls of the vagina as advised by Westermarck, this acted by hindering eversion of the vagina. Cases occurred in which all such operations failed, and in these ventral fixation and vaginal hysterectomy were not always effective.

In concluding, he grouped the operations as follows: (1) Tying up the uterus to a fixed point, ventral fixation, Alexander's operation; (2) Operation on the vaginal wall anterior, posterior lateral elytrorrhaphy; (4) Perineorrhaphy; (5) Resection of uterus or of both vagina and uterus.

Dr. Edebohls of New York, in continuing the discussion, said that in mild cases he performed ventral fixation, and in more severe cases, those of second degree, he added plastic operations to the ventral fixation, doing the following operations at one sitting: Curettage, amputation of the cervix, plastic operation on the vagina walls, and ventral fixation. One point in connection with the plastic operation to which he wished to call attention was the great advantage of bilateral colporrhaphy. In doing this he would leave on the anterior and posterior vaginal walls a strip of mucous membrane 1½ inches wide, removing all the mucous membrane on the lateral walls. By that means he obtained a vagina one inch in diameter. He had reported, eighteen months ago, four cases in which he had performed complete extirpation of the uterus and vagina for prolapse of the third degree, and all had been successful. Before performing this operation, one should always explain to the patient what was to be done. In performing it, he first made an incision round the vulva and then dissected up the vaginal walls, removing the uterus and vagina in one piece. He would leave the tubes and ovaries. This left a solid bulwark of tissue five inches deep with no peritoneum intervening. After removing the uterus and vagina he brought the raw surface together by circular sutures, tying them from above down, and pushing them up one after the other, then making a ring of sutures seven to ten in number. He used chromicized catgut. He allowed the patient to get up one week after the operation.

Dr. MacNaughton Jones of London considered retroversion of the uterus an important factor in prolapse. He thought the best operation was ventral fixation with amputation of cervix. He would amputate the uterus only when it was distinctly diseased.

Mr. Bowerman Jessett of London thought that one should be careful to explain the operation fully to the patient beforehand in cases in which it was intended to remove the vagina, otherwise a law suit might follow.

Dr. Smyly of Dublin said that there was no difference of opinion about the importance of restoring the pelvic floor, but there appeared to be a difference of opinion as to the part that retroflexion played in prolapse; personally, he thought that retroflexion with relaxation of the peritoneum was the first step in prolapse, and he considered that it was essential to cure the retroversion. He did not favor Alexander's operation, because in about one-fourth of the cases adhesions were present, which it was not possible to free by this operation. He preferred ventral fixation, or, in old women with small uteri, vaginal fixation. The hypertrophy of the cervix disappeared when the uterus was kept in position, and he had not usually found it necessary to amputate the cervix.

Dr. T. J. McCann of London divided prolapse into three classes: (1) Descent of uterus associated with prolapse of the vaginal wall; (2) Primary prolapse of the vaginal wall; (3) Primary prolapse of the uterus. For the first, if the anterior vaginal wall was involved, he did colporrhaphy, removing much tissue and using buried catgut sutures; if there was rectocele he performed extension of the perineum.

For relief of the second condition he performed supravaginal amputation of the cervix with colporraphy and extension of perineum. For the third he performed ventral fixation, attaching the round ligaments to the abdominal wall.

Dr. Inglis Parsons of London said that after ventral fixation, trouble in subsequent labor might ensue; in women past the child-bearing period this objection did not hold good, but in old women the abdominal wall was frequently so weak as to yield readily and be drawn inward. He had obtained excellent results from his method of injecting a solution of quinine into the broad ligaments, so as to excite inflammation and contraction in the fibromuscular bands in these ligaments, which, as proved by Professor Turner, offered the greatest resistance to prolapse. He had done this operation in si[illegible] cases, four-fifths of which were cases of complete procidentia. He used sulphate of quinine, 12 grains dissolved in three parts each of dilute sulphuric acid and distilled water.

Mr. Stanmore Bishop of Manchester had devised an operation by which he fixed the uterus in the peritoneum at the back of the pelvis near the rectum, so as to close the lower part of Douglas's pouch.

Dr. J. Tennant of Edinburgh had dissected two specimens of long existing prolapse and had found the peritoneum of Douglas' pouch extending almost to the perineum. In most of the operations this sac remained and might contain intestine, and the operation described by the previous speaker was the only one that had been mentioned which would deal with this pouch.

Dr. Y. Edge of Wolverhampton said that prolapse differed from ordinary hernia, in that the walls of the sac contained important organs which could not be sacrificed.

He had seen two cases of prolapse in virgins and had cured them by ventral fixation. In performing vaginal hysterectomy for prolapse, the peritoneum should be closed and the fascial structure brought together by sutures. He had performed complete extirpation of the vagina and uterus after the method which had been described by Mr. Christopher Martin of Birmingham, and found it best to strip down the vaginal wall while it was still attached to the uterus. He advised curetting, amputation of cervix, anterior vaginal fixation of uterus and double lateral colporraphy. Rest after operation was a great factor in the final cure.

Dr. Comyns Berkeley of London had seen good results from the operation described by Dr. Inglis Parsons.

Dr. Galabin of London pointed out that Dr. Hart had said little about the elongation of the uterus, which was so marked a feature in prolapse; this elongation was caused by the traction exerted on the uterus by the prolapsed vaginal walls, as was proved by the fact that the uterus became smaller again in the third stage of prolapse, when the uterus was entirely outside the vulva.

In his experience recurrence was liable to take place after all forms of operation, and he thought that the prolonged wearing of a Hodge's pessary after operation was advisable, and that the patient should have as long a rest in bed as was possible. He performed anterior and posterior colporraphy and endeavored to unite the fibers of the levator ani by a special form of suturing. He had done vaginal hysterectomy and united the broad ligaments afterward by suturing. This held up and prevented prolapse of the vagina.

He advocated Le Paul's method of making a double vagina by uniting raw surfaces on anterior and posterior walls, this allowed of coitus, but was not advisable in cases in which pregnancy might occur.

Dr. Berry Hart, in reply, agreed with Dr. Galabin that the elongation of the uterus was caused by the prolapse and was not a factor in its etiology.

Past and Present Treatment of Uterine Fibroids.—Dr. Murdoch Cameron of Glasgow read this paper. He did not believe that fibroids ever disappeared spontaneously. Not more than one-third of all cases required operation. He had obtained good results from oophorectomy in fibroids and advised that operation.

Professor Curatulo of Rome read a paper on "Special Treatment in Cases Peculiar to Women in Conjunction with the Muriated Iodo-bromine Water of Salso Maggiore." Dr. F. J. McCann of London read a paper on "Vaginal Fixation."

A vote of thanks to the President was proposed by Dr. Berry Hart, and seconded by Dr. Buist.

This concluded the business of the session.

(To be continued.)

Clinical Department.

A CASE OF MULTIPLE PERSONALITY.

By J. ALLEN GILBERT, Ph.D., M.D.,
PORTLAND, ORE.

After the article published in the Medical Record of August 9 had been submitted, among other developments of importance, there came to my notice a letter written by X at San Francisco to his grandparents at Crawford, Neb., November 6, 1900. In his letter sent to me by his grandparents, not only were they known to him, but his brother, uncles, and aunts at Crawford were mentioned by name. It will be remembered that it has been supposed all along that only as X1 and in his "united self" were his relatives known to him. X1 had said on April 2 that he knew nothing between the quarrel with his father at Glenrock, Wyo., in '99 and waking up in Portland on April 2, 1902. This letter appeared to be a blank contradiction of the above history. It was decided that either he had forgotten or misrepresented the facts as X1, in saying he knew nothing since September, 1899, and had on April 2 concealed his life at San Francisco, or else while at San Francisco he was at some time in what we have looked upon as his "united self," or in some other State in which his relatives were known to him. To decide this point it was determined to change him from his "united self," which we will hereafter call X1, 2, 3, into X1, and after questioning him in regard to San Francisco, to show him the letter. On June 4, in company with Dr. S. A. Robinson, who has shown great kindness and interest in the case throughout, I went to Vancouver, explained to X1, 2, 3 that, in order to verify a few things of great importance, it would be necessary to change him to X1, assuring him that he would be returned immediately afterward to X1, 2, 3. He refused blankly, on the ground that he did not want to run any unnecessary risk of losing again the memory of his whole life in exchange for the partial memory of either X1, X2, or X3. The importance of doing as we requested was argued in vain until after about one-half hour's explanation and persuasion, he finally consented. He was hypnotized with ease. To be assured myself, and to assure the officers present that he was completely hypnotized, after suggesting anæsthesia, he was stuck with a pin in the neck and hands till blood was drawn without calling out the slightest reflex. By the usual method he was changed into X1 on waking. He did not know the officers present. No clue could connect him with either X2, X3, or X1, 2, 3. He never had been in Vancouver, and on being told that he was now in Vancouver, arrested on the charge of desertion from the army, he denied the charge, and then retracted the statement, after a brief pause, by saying, "Yes, I must have deserted back at Chickamauga." It will be recalled that his arrest was for his desertion at San Francisco, and not at Chickamauga. At times, in his different personalities, his mind seemed clearer than at others, and he was now urged again to try to recall how he got back from Chickamauga to Nebraska. After thinking awhile, he said, impatiently, "It is no use trying to remember a thing I don't know anything about." He must have had, at least, a brief change of some kind at Green Brier, Tenn. Letters received from Mr. Pinson, the man for whom he worked for two days near Green Brier, stated that he acted very queerly there, and all at once he wanted to quit and leave and "claimed he was sick when he left, with stomach about to kill him." This looks like a change into X3. Mr. Pinson also wrote, "I am satisfied his mind was not balanced while he was with me," and looked upon him as a "deserter or convict," and also said in his letter "he would at times seem as if his mind was wandering clear off, would talk to himself at times, and I knew he was not the man I wanted, so I was glad to get rid of him." Mr. Pinson says that while there he used the name Charley Smith. He now knows nothing of having used that name. It is possible that this name may stand for another personality, which would fill the gaps still existing. He remembers distinctly having used the name "Peter Jones" at Edgemont, S. Dak., but says he assumed that intentionally to cover any possibility of pursuit by his father, who tried to shoot him at Glenrock, Wyo.

While X3, on April 24, in relating to me his experiences while working for a John Hunley at Springfield, Tenn., which was his next stop after Green Brier, he said Hunley told him that one time he wandered away and disappeared, and they were looking everywhere for him. This affair scared the women, and they told him if he ever did that again he would have to leave. He knew nothing of wandering away. This was in all probability another change. Evidence seems to indicate that there have been a great many changes of short duration, of which we are as yet in ignorance. A number of times he has spoken of dreams which were not dreams at all, but real, isolated experiences of short duration. At Oxford, Mascot, and Holdredge he undoubtedly had a number of changes, for he was looked upon as insane.

To return to the examination of X1: On being asked his age, he answered, "I ought to be eighteen, but you told me in the hospital in Portland that was not so." Hesitating again, and looking round him, when asked where he thought he was, he said: "Maybe I have dreamed all this. I ought to be in Glenrock, Wyo." And, as if to reassure himself, he reached over and touched my knee. In answer to questions, he said he never had been in San Francisco, but he remembered a dream he once had of being there. A few details of the "dream" were given, but it was hazy for the most part. He knew none of the officers at San Francisco when they were mentioned to him. In short, he was X1, and knew nothing that transpired since last being X1 in the hospital. I then gave him the letter in question, and asked him if he could tell me anything about it. He looked at it and said: "That's my handwriting all right enough." After reading the letter, he said, in a confused and hesitating way: "I must have been there, but I don't know anything about this letter." It was then explained to him briefly what had happened, and, in order to get his consent to be hypnotized again, so as to change him back to X1, 2, 3, the letter in his pocket and other evidence were brought to bear, and he readily consented. He was hypnotized easily, but not so easily as in previous attempts, likely because he had only been hypnotized twice in this personality. While hypnotized, as chance would have it, a cannon was fired just outside the guard-house. It startled us severely, but X never moved a muscle. It was then suggested he would wake as X1, 2, 3, and he did so. He was then shown the letter in question again, and asked if he knew anything about it. After scanning it partially, he said: "Yes, I wrote that at San Francisco while I was in the army there," adding other unimportant details. He now knew his officers at San Francisco at that time, and gave other details which were verified by one of the officers who was at San Francisco at that time, and who was now at Vancouver and present as a witness to the above.

At the time it was thought that the above showed conclusively that the letter in question was written while $X_{1, 2, 3}$, and note made in my record to that effect, supposing that only X_1 and $X_{1, 2, 3}$ knew their relatives; and it was also concluded in consequence of this that on April 28, instead of "uniting" his three personalities for the first time, we had merely brought to light a new personality which had existed at San Francisco. A later development on June 27 showed this supposition, however, to be incorrect.

On June 20 I received a letter from him written in prison at Vancouver the day previous, in which he says he "came to himself," and found the cell in disorder. The guards said he acted delirious for several days. $X_{1, 2, 3}$ had been in the habit of crossing off the days on his calendar as they passed, in order to keep account of the days of the week. The last three days were not crossed. In his delirium during these days he at times chased red devils. This was probably a change to the state of delirium described above.

On June 25, 1902, he was released from prison and discharged from the army. After a ride home with him on the electric car from Vancouver Ferry, Dr. Robinson and I left him as $X_{1, 2, 3}$ near his home, with the promise from him that he would come to my office the next day by noon. He did not come. I searched for him, but did not find him at home, and met him, while searching, on June 27. When asked why he did not come to my office, he said he was afraid to come any more, because he had a horrible dream night before last, and he decided he had better stay away from me. He knew nothing of promising me on the car to come to my office, nothing of his imprisonment at Vancouver (except what he thought was a dream), nothing of the beard which he had involuntarily raised while in prison, etc. In short, he was X_2 again. The dream he had was hazy, but he said he was behind bars, and the guards made fun of him. There were a great many soldiers there. Mrs. Gilbert and I were there, too, and I had something to do with his imprisonment. This "dream" will be readily recognized, not as a dream, but as his real experience at Vancouver when I went to present his case to the officials, May 16, at which time Mrs. Gilbert was with me. At that time, it will be remembered, I found him changed to X_2 and changed him back again to $X_{1, 2, 3}$.

After finding him in X_2 now again, we walked to his scow near by. On the way he spoke of his relatives. With my attention on the subject under discussion, I did not notice the seeming inconsistency of his knowing his relatives at Crawford till later, after he was again changed to $X_{1, 2, 3}$. On April 1 he gave the history of not knowing his relatives, except his father and brother, and did not know the name of the latter. It will be remembered that at that time his memory was fragmentary and incomplete, due, probably, to the concussion of brain received in the large accident. All through the development of the case, the supposition has been acted upon that he did not know his relatives, but this has evidently not been the case, and it leaves but little doubt that the letter in question was written as X_2 while in San Francisco.

After explaining to him briefly what had happened, I again hypnotized him and by the usual method changed him to $X_{1,2,3}$. He woke as $X_{1,2,3}$, and knew all as before as well as his prison experience, discharge, experience as X_2 since his discharge, etc. After leaving me on the car as $X_{1,2,3}$, June 25, he had gone to his scow, unpacked his valise and then went up town to get shaved. He retired that night and woke as X_2 next morning. The dream he thought he had made him avoid me. He thought it was May instead of June, and everything was awry. For the sake of brevity numerous interesting details must be omitted.

On July 3, while sitting talking to a companion, X suggested that they go down town. All at once, he says, without any knowledge of time having elapsed, here stood his companion before him with clothes changed ready to go down town. Evidently this was another short lapse, not of sufficient moment to attract the attention of his companion. Evidence points to numerous short lapses in past years.

On July 25, about 8 P.M., X came up the street toward my home greatly bewildered and staggering like a drunken man. I called to him before he saw me and asked him what was the matter. He started, looked at me rather wildly, and after leaning against the post of the porch for support, said, "They told me to ask you if the cows had come home." Then manipulating his fingers as if to imitate some contrivance, he said, "I know it will work all right." During the next hour he said repeatedly, "I feel terrible sick," and his looks showed that he was. On being questioned he said he had seen Mrs. Gilbert and me somewhere, but did not remember our names, and, by way of explanation, added that he at times forgot names. When urged repeatedly to tell us what month this was, he at last said: "Oh, I don't care much." Numerous questions were pressed upon him, but his answers were evasive; most of the time he would not answer at all. He insisted upon leaving several times, in a way which indicated that he did not fully realize where he was or where he belonged. I urged him to sit down because he was sick, to which he responded, "Yes, but I am not crazy. They made fun of me, but I don't care," but the distress in his face showed that he did care. His eyes were blood-shot. He felt chilly, but this was due to the sudden cooling of his sweated shirt after being overheated, as developed later. I began taking his pulse and temperature. While holding his wrist to count his pulse, he dropped asleep. I spoke to him and tapped him on the knee. He woke with a start, was $X_{1, 2, 3}$, smiled and said, "Well, how did I get in here anyhow?" His pulse before and after waking was 99 and 90 respectively. His temperature after waking was normal. The last he could remember was being accosted at 2 P.M. by a man who hired him to fire the engines in the Portland Hotel. At first he could not recall where it was he had been hired to fire, did not know the man who hired him and could only remember starting off with him. After thinking a few minutes he remembered that it was at the Portland Hotel he was to work.

He still felt sick at the stomach and said a lemon was the only thing that would relieve him. It was given him, and he ate it almost ravenously, saying that at first it tasted sweet, only becoming sour toward the last. He said that while firing for the West Coast Furniture Co., at San Francisco, he had such a spell and ate six lemons before he was satisfied. At Mascot he always carried lemons in his lunch pail. This throws light on the peculiar circumstances at Oxford, Mascot, Holdredge, and San Francisco, making it highly probable that the gaps still existing in the schedule would be filled by this semi-delirious state if they could be obtained.

After eating the lemon he felt better, became more serious and thoughtful and said, "Oh, well I've been asleep again, that's all." When he left for home he was very blue and discouraged. Inquiry next day at the Portland Hotel revealed that he had worked there, had been a good hand, and was all right so far as they could detect, except that about 7.30 P.M. he left without saying anything to any one.

He probably came directly to my house. It was exceedingly hot where he worked. The next day X was in good spirits again. His experience of going to the hotel with the man and working there came back to memory, but minor details were still wanting.

In order to make the schedule complete to the present time, the following data should be added:

X1,2,3. Hypnotized April 29. When questioned in regard to the existing gaps he passed into

**f. A state of semi-delirium. Put to sleep and changed him to

X1,2,3. Arrested May 14. Taken on car to Vancouver, Wash., changed to

X2. Hypnotized May 16 and changed to

X1,2,3. Hypnotized June 4 and changed to

X1. To verify the letter in question. Hypnotized and changed to

X1,2,3. While in prison on June 15 changed to

**g. A state of semi-delirium. Changed June 18 to

X1,2,3. Discharged from the army June 25. Came home on car. Changed that night to

X2. Hypnotized June 27 and changed to

X1,2,3. Had a short lapse July 3. On July 25 changed to

**h. A state of semi-delirium. Changed to

X1,2,3.

I had hoped to get his consent to hypnotize him and change him to X2, in order to question him in regard to the letter written at San Francisco, but he seems reluctant and the point can be reached later perhaps. Though he, with justice, resents being hypnotized unnecessarily, yet what has been done has always been done with his full consent and, though he has not given his consent to submit himself for further study, he does not seem entirely averse to the idea. Should opportunity present, a more thorough investigation of the separate personalities and their relation one to the other with reference to suggestion and many other pyschological problems will be made. There are indications that a study of his dream life would also be exceedingly instructive.

A CASE OF PREMATURE DELIVERY WITH UNUSUAL TEMPERATURE COURSE.

By ANNA E. BLOUNT, M. D.,
OAK PARK, ILL.

On April 28 I was called to a woman whose confinement I had expected in July. The patient, a young woman of twenty-four years, had been married the preceding October, and had not menstruated afterward. She had been a stenographer, and was of a nervous temperament. She gave a good family history, and her only acute illness had been typhoid fever, two years previously. During the preceding August and September I had treated her for frequent and aggravating attacks of pain in the right lower abdominal quadrant. She appeared to have no enlargements of tubes or ovaries, but a slight thickening and tenderness in the right fornix. She had a retroflexed uterus. The chest examination showed dulness of right apex. She had had a winter cough for several years.

On arriving at the patient's bedside I found her having moderately severe labor pains, their strength waning. She complained of excruciating pain and tenderness over the right upper part of the abdomen. An area the size of her palm was exquisitely tender. Pains had begun with a sneeze, which made her hold this side especially. Temperature 98.6°, pulse 100°. She had been taking quinine and hot baths for a cold in the head. She was unable to take nourishment without vomiting. The child presented vertex, L. O. A., and was living.

I gave anodynes, and the pains ceased by the next morning. There had been no flow. Temperature 100.5°, pulse 104. In the evening of this day, temperature was 99.5°, pulse 100.; no pain. The woman felt quite well.

On the morning of the third day she had a slight chill and the temperature rose to 103°, pulse 108.

On fourth day, the morning tempertaure was 97.6°, pulse 100; evening 100°, pulse 110. The urine of this day showed albumin and hyaline and granular casts.

Three weeks previously the urine had been normal, with high specific gravity.

On the fifth and sixth days there was no pain, and a slightly subnormal temperature prevailed. During the evening of sixth day of illness there was a severe chill, two more the next morning, and the temperature rose to 103°, pulse 120. Labor pains had returned, and the patient vomited.

I called Dr. J. W. Tope in consultation on the eighth day, the temperature course on this day being as follows: 1 A. M. 103°; 9 A. M. 97°, pulse 100; 9 P. M. 100°. On the following, or ninth day, at 2 A. M., the temperature was 95°; at 8 A. M. 96.8°; at 4 P. M. 97.6°.

Acting upon the advice of Dr. Tope, I resolved to terminate the difficulty. The pains had subsided again, and on the evening of the ninth day, having secured a nurse, I dilated with Barnes' bags, after douching with 1 per cent. orthoform. Dilatation occupied one and a quarter hours, was somewhat painful, but was well borne.

After the patient was put to bed, pains promptly ceased, but returned after thirty-six hours. The patient's temperature was 96.6° to 97.6° during this time. (Rectal temperatures showed a degree higher in each instance.) On the twelfth day the pains continued all day, but subsided at midnight, having produced very little dilatations, but some descent. The fœtus was lying obliquely, head and shoulder partly descended, into the pelvis, both hands palpable through the membranes. The patient was much exhausted, but rested during the night.

The next morning there were a few pains, and the child was still living. Patient's temperature was 97.2° at 10 A. M., when she was anæsthetized. I had the patient carefully prepared, and after complete anæsthesia had been secured I redilated the cervix manually, taking turns with an assistant at this wearisome process.

I found the hand and shoulder presenting, and the head on the right above the brim, both hands being palpable through the membranes.

By combined internal and external manipulations I pushed up the shoulder and brought down the breech. The feet, however, I could not grasp, and after many attempts to get a foot, I delivered by pulling on the breech, one forefinger hooked into either groin. The child, a female, weighing one and a quarter pounds, was dead.

I carefully separated the placenta by the fingers, but found one portion so much softened that it could hardly be kept intact.

This portion was the site of a disintegrating bloodclot. We had previously considered it likely that we should find placental hemorrhage. The patient suffered no hemorrhage. Her temperature was 100°, on the evening after the operation, but on the following morning was 98°, and from that time on was practically normal. The urine on the seventh day after delivery showed a trace of albumin, and a single hyaline cast was found.

The striking features of this case were successive hilis and an irregular temperature course, from o4° to 95°, due to placental hemorrhage.

The mother of the child had never shown any ymptoms of syphilis, but the father had been reated five years perviously for tertiary lesions, hough he knew of no primary lesion.

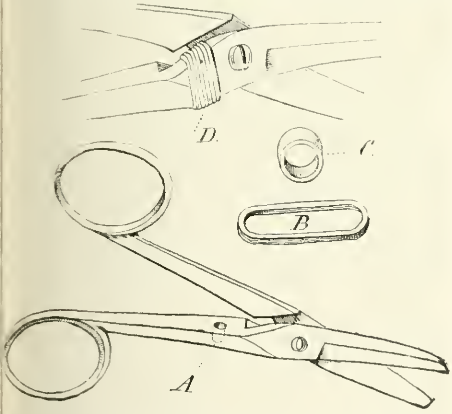
New Instruments.

N INSTRUMENT TO INCREASE THE SCOPE OF COCAINE SURGERY.*

By FREDERIC GRIFFITH, M.D.,
NEW YORK.

SURGEON, BELLEVUE DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

HERE are many associated factors at work in a uccessful cocaine operation. While it was formerly irected that only by using solutions varying in trength between 4 per cent. and 10 per cent. of this rug could we hope for a satisfactory result in the roduction of localized anesthesia; it has remained or surgeons during the past few years to demonstrate the fact that according as one is able to impress upon the mind of the patient the knowledge f his power to perform a painless operation, to the ame degree can he reduce the percentage of ocaine in solution. By this means there are a umber of surgeons in town who habitually employ ocaine in strength of ½ to ⅛ per cent. down to a nere infiltration of the tissues after the initial uncture has been made by the weak soda solution sed as a diluent, and are thus enabled to perform perations which many would not contemplate vithout the use of general anesthesia.



During the performance of a cocaine operation he patient is in an abnormally active, receptive rame of mind. Keyed up to a high pitch of expectant incredulity the various proceedings of the urgeon, his manner, words, the tone of his voice, an in an instant change success into failure, and it s in this direction, to decrease the chance of an dverse conception being made, that the instrument o be described is intended.

Scissors are now used by some surgeons to the xclusion of knives for ordinary work, and in the eld of cocaine surgery, save for one fault, namely, he clamp of the blades, they become indispensable. he click of the steel is unnoticed by all save the atient, but questioning will show that he is taking lively interest in that irritating noise, and there re a certain number of individuals in whom this ne thing will decide for failure or success.

To reduce the noise of the working blades to a minimum I have devised an appliance which can be attached to any form of scissors; a rubber burr is to be fitted behind the joint of one handle (*A*). The hole is to be drilled one-fourth of an inch behind the joint and to be three-sixteenths of an inch in diameter for ordinary sized shears. In depth it should extend nearly through the handle, and a plug of rubber long enough to stand out from the surface one-eighth of an inch is to be inserted. Acting thus as a buffer, the plug retains its place by reason of its own elasticity, if made slightly larger than the diameter of the hole.

Sterilization of the instrument by boiling will not interfere with its practicability, as the rubber plugs may be easily renewed.

A method by which a similar result may be obtained from a piece of thin rubber tubing, or an ordinary elastic band, applied over the joint of the female blade of the detachable scissors commonly in use is pictured in figures *B*, *C*, and *D*.

805 Madison Avenue.

AN AMPUTATING RETRACTOR.

By ELWIN C. TAYLOR, M.D.,
SCRANTON, PA.

HOUSE SURGEON, MOSES TAYLOR HOSPITAL.

Many operators have wished for a suitable amputating retractor, but still use the two- or three-tailed bandage. The bandage retractor does not steady the part, retracts poorly, and always catches the saw unless the assistant's fingers are interposed.

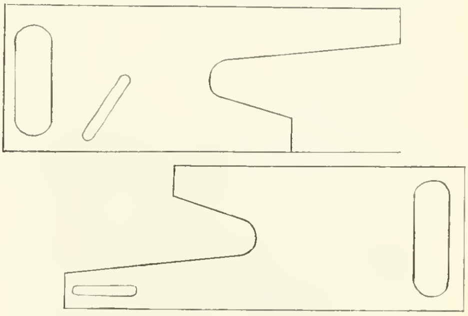

FIG. 1.—RETRACTOR PLATES.

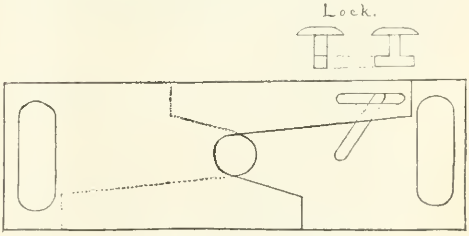

FIG. 2.—RETRACTOR PLATES IN POSITION.

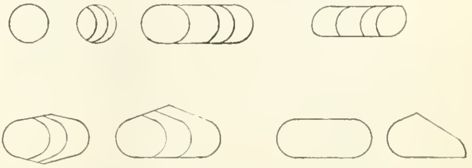

FIG. 3.—RETRACTING APERTURES OBTAINED BY THE INSTRUMENT.

The instrument as designed by the writer is eleven inches long, four inches wide, and is made of spring steel one-eighth of an inch in thickness. The figures illustrate the construction and mode of application of the device.

Its advantages are that it is (1) easily cleaned and sterilized; (2) retracts evenly; (3) holds the part teadily while the operator is working; and (4) is djustable to size, shape, and ridges of bones amputated.

Therapeutic Hints.

Medical Treatment of Tuberculous Peritonitis.—According to Yeo, over 50 per cent. of cases recover. Persistance in the local application of equal parts of iodoform ointment and cod-liver oil is of extreme importance. A mixture of 15 gr. bismuth salicylate, 15 mm. spr. chloroform, ½ ʒ comp. tinct. cardamom with mucilage and water will relieve pain and allay intestinal irritation.

Simple Feebleness of Heart.—This condition is particularly met with in older people whose powers are beginning to wane. Heart sounds are normal, but when at rest the pulse is feeble and irregular. The irregularity is ascribed to interference of feeble pulse waves, in a low-toned and badly-filled channel. *Cardiac drugs are contra-indicated.* Rest, good food, pleasant occupation, and a general tonic will bring about complete restoration.

Tapeworm.—The patient fasts two days, and on evening of second day takes a purgative dose of castor oil, and the next morning, while still fasting, takes an ounce of slippery elm bark in half a pint of water, and repeats in half an hour with a full dose of oil.

Orchitis.—For the pain in orchitis quinine sulphate, gr. viiss. internally, and the following locally applied:

℞	Methyl salicylate	ʒvi
	Guaiacol	ʒi
	Vaselin	℥i

—Lutand.

Neurasthenia.—

Chlorid gold and sodium	gr. $\frac{1}{10}$
Guaiac. resin	gr. v

M. ft. in cap No. 1.
S. One capsule before each meal. —Brower.

Goiter.—Hydrastis canadensis is recommended after experiments on a series of twenty-five cases. The period of cure lasted from six weeks to three months. The drug is given three times daily after eating.

—William Cuthbertson.

Spasmodic Os Uteri.—Chloral hydrat gr. xv to ʒi every quarter of an hour is of decided use. Morphine hypodermically is of great use where the spasm is combined with great maternal exhaustion. —Marx.

Feeble Uterine Pains in Second Stage.—Sugar is used as a muscular stimulant, the patient being given several lumps to eat. Quinine muriat gr. x by mouth or rectum, is of great aid. —Marx.

Prostatic Congestion.—

℞	Potassii iodidi	gr. v
	Icthyol	gr. iii
	Morph. hydrochlorat	gr. $\frac{1}{6}$
	Ext. datura	gr. $\frac{1}{6}$
	Cocoa butter q. s.	

M. ft. suppository No. 1.
S. Use one or two suppositories daily.

—Stordem.

Meat and Fish Poisoning.—

℞	Sol. hydrarg. perchlorid		♏xx
	Potassii iod		gr. v
	Chloral hyd		gr. v
	Ac. carbol		gr. i
	Spts. amon. aromat		♏xx
	Aq. chloroformæ	q. s. ad	℥i

M. S. One dose every three or four hours till effects are gone. —Arthur P. Luff.

Pleuritic Pains.—

℞	Menthol		ʒss
	Guaiacol		
	Camphor		
	Chloral		
	Methyl salicylate	aa	ʒi
	Lanolinæ	q. s. ad	℥i

M. S. Rub a small quantity into the skin over the lesion and cover with oiled silk. —W. J. Robinson.

Thrush.—Sodium sulphite solution, ʒi to ℥i water, if applied to mouth and tongue thoroughly, will usually cut short an attack. —Wm. J. Robinson.

Facial Neuralgia.—Give six drops every six hours of a mixture of equal parts of the tinctures of belladonna, aconite root, and colchicum seeds. —Medcalf.

Persistent Vomiting.—This symptom is in most cases checked by repeated small doses of calomel, gr. $\frac{1}{10} = \frac{1}{12}$ fifteen minutes. *Medical Summary.*

Superficial Burns.—

℞	Thymol		gr. 1½–2
	Aq. calcis.		
	Oil lini	āā	℥iii.

Apply to burn. —Wertheimer.

Constipation.—

℞	Fl. Ext. cascara sagrada	ʒi.
	Glycerin	ʒi.
	Tr. gaultheria	ʒi.
	Tr. cinnamon	ʒi.
	Tr. lemon	ʒi.

M. Sig. ʒi. sufficiently often to keep bowels regular. Note.—Generally one dose two or three times per week is sufficient. —Geo. J. Monroe.

The Treatment of Prolapsus Ani in Children with Paraffin Injections.—Karewski has treated eight cases of prolapse of long standing and which had resisted other methods of treatment by injecting a ring of paraffin (melting point 56 to 58°C.) above the anus. The patient's bowels were kept open with laxatives for two days, and then, on the afternoon of the day before the injection, were checked by giving him 15 to 30 grains. of bismuth. After disinfecting the operative field the prolapse was reduced and one finger kept in the rectum. Using it as a guide, a ring of paraffin was then injected around the anus between the skin and mucous membrane, only a single needle puncture being made. Bismuth was again administered to prevent defecation during the next twenty-four hours. Of the eight cases treated in this way only one failure is reported, and no infection occurred in any of them, even when defecations followed immediately after the operation.—*Centralblatt für Chirurgie.*

Contagious Diseases—Weekly Statement. Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 23, 1902:

	Cases.	Deaths.
Measles	63	2
Diphtheria and croup	158	25
Scarlet fever	76	7
Smallpox	5	1
Varicella	4	..
Tuberculosis	209	134
Typhoid fever	119	20
Cerebro-spinal meningitis	..	3

Opium Dangerous in Pneumonia.—I regard opium as a drug of extreme danger in pneumonia. I am aware that men of great eminence have taught otherwise. But, in so representing the case, I am not advocating any theory, but rather am dealing with facts which I know to be true, and which, if true, are such as ought to be in the mind of every practitioner. I have repeatedly seen what can only be regarded as poisonous effects from very moderate doses of opium in certain stages of pneumonia; and (especially toward the crisis) have learned to dread it more than almost any other drug. One case of this kind occurred some years ago in the Western Infirmary, and might well have been published at the time, by way of caution, had I not been anxious to spare the feelings of my excellent assistant, who (if I were to name him now) would be recognized by every Glasgow student of that time as one of the best men in the profession, whose premature death, some years later, was the cause of universal and deep regret. The case in question was this: A man in the prime of life, and otherwise quite sound, had acute pneumonia of the lower lobe of one lung, which was running an average course, up to (I think) about the sixth or seventh day from the rigor. I had left him in a fairly good condition, but with considerable pain, which increased during the night. Next morning he was cyanotic, with slow intermittent breathing, and a very feeble, unsatisfactory pulse. His pupils were somewhat contracted. "Has he had any opium?" I immediately asked. "Yes; one-sixth of a grain of morphia, hypodermically injected, for the pain." The whole scene was such as, I am sure, will never be forgotten by those who witnessed it. My poor assistant was almost thunderstruck, but there was no time to be lost; and, by the usual means, we just managed to pull the patient through a most perilous crisis, after which he recovered without any relapse or any further incident. Now, this is a fact to be related, apart from all hypothesis. And yet it is not at all difficult to find a legitimate theory to fit in with, and account for, the fact. In pneumonia, far more than in pleurisy, more even than in bronchitis, the safety of the patient depends upon the respiratory nerve-centers being kept, as it were, wide-awake. The greatly accelerated breathing—"accelerated without being laborious," as I used to point out as a rule —is practically at once the index of the danger, and the means by which Nature compensates for the restricted area of lung within which the air can meet the circulating blood. If then, when the respirations are 60, or even 50 or less in the minute, the respiratory nerve centers are sent to sleep by a potent narcotic, is it not obvious that the influence exerted at a critical time must be unfavorable? But opium is, of all narcotics, the one that tells most rapidly on the respiratory nerve centers, and thereby not only on the reflexes dominating the overt respiratory acts, but on all the more latent reflexes which are concerned in what I have constantly termed the "scavenger action" of the bronchial tubes, due to their circular muscles. In the above case (as in others which I have witnessed) all this essential machinery, working at high pressure to keep the patient in life, is brought to a comparative standstill, while the disease is still proceeding, or at least not retreating. Can we wonder at the result? I give this theory tentatively, not dogmatically; but of the facts I am absolutely sure, as above stated. If strychnine and the older remedy, antimony (as to which I must even now speak with caution), are good for anything in these circumstances, it is because they tend to keep these respiratory reflexes in full operation, which even a moderate dose of opium would paralyze or abolish.—SIR W. T. GAIRDNER in *Glasgow Medical Journal*, April, 1902.

Modern Methods Employed in the Prevention and Treatment of Trachoma and Other Forms of Contagious Ophthalmia.—Karl Koller speaks of the treatment of gonorrhœal ophthalmia, of diphtheritic conjunctivitis, and of trachoma. In gonorrhœal ophthalmia of the adult, the first concern is to prevent the spread of the infection. The patient should be isolated and put to bed. The room should not be dark. If only one eye is affected, the other is covered with a protective bandage, which should be changed every three or four days. The eye should be thoroughly cleansed of all discharge as soon as it accumulates. Sometimes it is necessary to rinse the eyes every fifteen minutes, day and night. Kalt has introduced irrigations of the conjunctival sac with large quantities (up to one quart) of a 1:5,000 solution of permanganate of potash; or a solution of 1:2,000 formalin, or sublimate 1:5–10,000 can be used. The solution must be warmed. These irrigations may be used every two hours, day and night. If cold applications are not well borne, hot ones should be tried. Nitrate of silver is the sovereign remedy in this affection. In the new-born, as soon as a case of this kind comes under treatment, nitrate of silver ought to be applied in 2 per cent. solution. The lids should be well everted, and brushed with the solution until they are well whitened. This ought to be repeated every day. Every half hour the lids should be separated and the discharge washed away by expressing a cotton swab, saturated with boric acid. Kalt irrigates the eyes two or three times a day with 1:5,000 permanganate solution, using a quart each time. In diphtheritic conjunctivitis hot applications should be made from the beginning. The discharge should be removed as often as it accumulates. After five or six days of infiltration, nitrate of silver is used, in 1 per cent. solution, and this most carefully. It must be stopped if membranes or infiltration reappear. Corneal ulcers are treated according to general principles. Prophylaxis is important in trachoma. Nitrate of silver and sulphate of copper are trustworthy remedies. The expression with roller or other forceps is now in almost universal use. General anæsthesia should be used. Whereever the conjunctiva is atrophic, expression should not be done. After this operation a ½ per cent. solution of silver nitrate is to be applied to every part of the conjunctiva. A bandage should be applied and kept on over night. It will prevent the œdematous swelling. A 2 per cent. solution of $CuSO_4$ in glycerin, used from four to six weeks, will, in most cases, cause the entire disappearance of follicles and papilæ. In all cases of acute inflammation liberal scarification of the conjunctiva will be beneficial. In cases in which atrophy and cicatrization of the conjunctiva exist, the follicles may be expressed between the nails of the two thumbs. This is far less injurious than the forceps.—*Pediatrics.*

Popular Errors.—That man, as an individual or in the aggregate, is prone to believe all kinds of statements, without the slightest evidence as to their correctness, is a well-known psychological fact of every-day observation. There is an amusing illustration of this in "The Life of Charles Darwin." A gentleman, who it appeared later was a good local botanist, wrote to Darwin from the Eastern Counties that the seeds or beans of the common field bean had that year everywhere grown on the wrong side of the pod. Darwin wrote back asking for further information, as he did not understand what was meant, but he received no answer for a very long time. "I then saw," Darwin goes on to say, "in two newspapers, one published in Kent and the other in Yorkshire, paragraphs stating that it was a most remarkable fact that 'the beans this year had all grown on the wrong side.' So I thought there must be some foundation for so general a statement. Accordingly, I went to my gardener, an old Kentish man, and asked him whether he had heard anything about it, and he answered, 'Oh, no, sir, it must be a mistake, for the beans grow on the wrong side only in leap year.' I then asked him how they grew in common years and how in leap years, but soon found that he knew absolutely nothing of how they grew at any time, but he stuck to his belief. After a time I heard from my first informant, who, with many apologies, said that he should not have written to me had he not heard the statement from several intelligent farmers, but that he had since spoken again to every one of them, and not one knew in the least what he had himself meant. So that here a belief—if, indeed, a statement with no definite idea attached to it can be called a belief—had spread over almost the whole of England without a vestige of evidence." Dr. Poore records an interesting instance of the same kind of thing in "Medical Jurisprudence": Whilst dining with five or six military gentlemen, all men of standing in the army, and one of them a colonel in the Engineers, the conversation turned on the growth of hair after death. Dr. Poore expressed the opinion that, theoretically, such growth might proceed for a few moments after death, but that was all. The Engineer colonel turned around and said, "You are perfectly wrong; there is no doubt whatever that in the Crimea the beards of the soldiers grew through the collars of their greatcoats." Further questioning showed that this estimable officer, who was incapable of a joke, especially on such a subject, had got it from a lieutenant who had got it from a captain; the captain had been told by somebody who had himself been told by Tommy Atkins. Of course, the notion that the beard could grow through the collar of a greatcoat is wildly absurd, yet here were educated people thoroughly believing in it. And the worst of it is that, like the old Kentish gardener, they, no doubt, stick to the belief.—*British Medical Journal.*

A Human Incubator.—A Kentucky farmer, Filson by name, lay sick with a fever, so high, the account goes, that it notably heated the whole bed-coverings. He was the breadwinner of the family, but his wife was a resourceful woman. Seeing her husband's energies going altogether to waste in uselessly raising the local temperature of his immediate surroundings, the thought occurred to her of a way of utilizing them to her and her family's profit. Borrowing some four dozen eggs, she placed them in the bed, securing them from danger of breakage by some simple arrangement, and in due time hatched out in this novel incubator forty-four chickens, to the great delight of the father of the family and herself. Perhaps the emotional condition influenced the disordered heat centers, for it is said that with the appearance of the newly-hatched brood the fever subsided, at least this is an allowable *post-hoc* conjecture. Continued fever is not a pleasant matter, as a rule, but the woman of the above story, which is given as a veritable history, deserves credit for her ingenious utilization of adversity, and the conclusion certainly is cheerful. Father and chickens are reported as crowing over their outcome.—*Journal of the American Medical Association.*

Information Wanted.—We are told that the New York medical profession, which has been in a state of disruption lo! these many years, is to become as a band of brothers at last, and there is to be no one hurt in the mix-up; that is, there will be no "defeat," no "victory," no "lying down of the lamb within the lion." Well, now, in the language of our old friend "Uncle Josh Weatherby," do tell us how this wonderful feat has been or is to be accomplished. It is a piece of parliamentary or diplomatic gymnastic work that we have never heard of before, and would be glad to know something definite about the *modus operandi.—American Practitioner and News.*

Hygiene of Churches.—The Bishop of Fano in North Italy provides for the association of cleanliness with godliness in his instruction to pastors; an example which might well be emulated in religious circles generally. In all churches, after feast days on which unusual numbers of people have congregated, the floors are to be cleansed with a sublimate solution 1-1,000. At least once a week pews and confessional benches must be wiped with a damp cloth, and the grating of confessionals washed with lye. The appurtenances of the altar are likewise to be cleansed with lye or sublimate.—*The Sanitarian.*

Consumption of Beer in Germany.—The Statistical Year Book of Berlin shows that the consumption of beer per individual increased from 199 liters (about 44 gallons) in 1895 to 232 liters in 1900. The corresponding figures for all Germany were 115 liters in 1895 and 124 liters in 1900. The Bavarian average in 1899 was 247 liters. The Berliner thus overdrinks the average German and underdrinks the Bavarian.—*New York Times.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 23, 1902:

ORGANACIDIA GASTRICA.

By MARK I. KNAPP, M.D.,
NEW YORK.

THIS article is to be looked upon as rather being a preliminary report. Whenever mention is made of experiments, in parentheses, I refer to experiments made by me, but which have not yet been published.

Of all diseases of the stomach, organacidia gastrica is fully entitled to take first rank in importance, as it takes in frequency. This disease derives its name from the presence in the stomach of organic acids, but to produce symptoms such acids must bear a certain relation to the HCl. Based upon my experience, I should judge that the number of the victims of this disease reach into the hundred thousands. Organacidia gastrica is a disease so common, and of such characteristic symptomatology, that rather its non-discovery hitherto should cause surprise. The reason that this disease has not been recognized can be attributed only to the fact that there were no exact, ready means to demonstrate such organic acids unless by very cumbersome, time-consuming, chemical analysis, requiring the skill of an expert chemist. The indicators now universally used in titration are faulty, so are the test papers. In my article of "Some New Facts in the Chemistry of the Stomach" (*American Medicine*, March 22, 1902) the fallacy of both dimethylamidoazobenzol and congo is proven. Both these dyes not only react on free inorganic acids, but also on free organic acids, and the dimethyl reacts even on the monophosphates of calcium and magnesium. It is but natural that in using fallacious tests fallacious results were obtained. Congo paper as a reagent for free HCl is not only useless, but misleading, and I have discarded its use. An imaginary deep blue color of the congo paper—in reality a gray blue—has been interpreted to indicate excess of HCl—hyperchlorhydria—whilst, as a matter of fact, such color means organic acids, which is very often accompanied by hypochlorhydria. Organacidia gastrica is always a matter of relative hyochlorhydria, although HCl *per se* may be found in sufficient quantity. My observations seem to justify the assumption that real hyperchlorhydria is not of so frequent occurrence. Fallacious tests led to fallacious diagnoses; fallacious diagnosis to fallacious treatment, and fallacious treatment led to the recognizing of the frequent occurrence of neuroses of the stomach. Whilst a good many cases came to me with a diagnosis of nervous dyspepsia, I myself could not corroborate such diagnosis, nor could I ever make such a diagnosis myself. When the causes of this disease are considered we see the reason why this disease is so common. As in diseases of the stomach generally, so also here can a positive diagnosis be made only after examining the stomach contents. So characteristic very often is the physical appearance of the aspirated chyme that a proper appreciation of it will help us greatly in making the diagnosis. The microscopic examination should be made a matter of routine. It is true that this disease can be diagnosed just as easily, indeed, even more readily, by the microscope, but not every practitioner enjoys the pleasure of owning an expensive instrument. However, the diagnosis by the microscope not only corroborates the chemical examination, but, quite occasionally, we may not aspirate enough for a chemical analysis, and for that reason a knowledge of the microscopical picture is very important. There is always enough of chyme on, or in, the stomach tube for a microscopical examination.

The presence of organic acids in the stomach, which constitutes this disease, manifests itself, clinically, in a symptom-complex only when there is a disproportion between the organic and the free hydrochloric acids. Normally, there should not be any, or possibly only a trace of, organic acids, and with the normal quantity of free HCl a small quantity of organic acids may cause no inconvenience. But when the quantity of organic acids increases or the free HCl diminishes in quantity, distressing symptoms will be elicited clinically. The same absolute quantity of organic acids may not cause any inconvenience in one case, yet be productive of distressing symptoms in another; it is always a question of relation between the free HCl and the organic acids. It would not be well or scientific to say how much of organic acids and how much of free HCl can be present in the stomach without giving symptoms; exact figures cannot be given—at least not as yet. Organacidia gastrica *per se* need not have any pathologico-anatomical changes; it is a pathologico-chemical disease. But whilst there are no pathologico-anatomical changes at the beginning of the disease, the gravest conditions may be the sequelæ. And because this disease is a pathologico-chemical one and because suitable quick tests for the recognition of such organic acids had not been known, the discovery of this disease had so far successfully retreated before the searchlight of critical investigation. In the absence of anything definitely demonstrable the symptoms caused by organacidia gastrica have been adduced to the mythical presence of neuroses of the stomach, a diagnosis, surely not in accord with the axiom of "survival of the fittest."

Organacidia gastrica is a collective term, and can be subdivided into three distinct classes: (1) Organacidia gastrica simplex; (2) Gastrosis fungosa, and (3) Zymosis gastrica. Whilst the symptoms of all these three classes are caused by organic acids it is not the same organic acid that causes the symptoms in each class, nor are the symptoms identical. The first, organacidia gastrica simplex, is to designate the transient presence in the stomach of organic acids in either absolutely or relatively large quantities. It is caused by the ingestion of large quantities of organic acids as contained in fruits, salads, pickles, strong cheese, etc. The symptoms are transitory. The vehemence with which this disease will manifest itself will vary with the amount of noxious material in the stomach. It may vary from a slight heartburn to violent cramps and vomiting, from insignificant gastralgia to severe cardio- and pyloro-spasmus. As a rule, the symptoms will disappear after the use of an emetic or cathartic. Beyond this medication and a little rest to the stomach nothing is necessary. Very often I have seen violent cramps, a temperature of 104°, or even 105°, accompanied by cold sweat, disappear after a suitable dose of calomel. It is different with gastrosis fungosa and zymosis gastrica. These are diseases of a chronic character. Nevertheless, both these conditions are amenable to successful treatment, and if uncomplicated can be cured in about two months, often in less time. But when complications exist, which are usually sequelæ to these diseases, the treatment may have to be greatly prolonged, in some cases the cure may be possibly altogether problematical. As a whole, I believe I am justified in being optimistic as to the cure of these diseases, once they are recognized and identified.

The most frequent disease of the three (possibly only in our geographical position) is gastrosia fungosa. In contradistinction to gastritis I want to introduce the term gastrosia. The term gastritis suggests an inflammatory condition, recognizable anatomically; the term gastrosia is to designate a pathologico-chemical condition. Fungosa implies, derived from, caused by fungi-mold, so that gastrosia fungosa signifies a pathologico-chemical condition of the stomach due to the presence of mold. I believe there may be several varieties of mold present in the chyme, but so far I could differentiate but two varieties as most often occurring in the stomach. Macroscopically, one is yellowish green and the other is dark red. In microscopical quantities I have never missed seeing mold or its spores in the aspirated chyme. In fact, mold has been found in every part of our body; in the blood, in the lungs, in the ear, in the nose, in the urine, in the skin, in new growths, etc. Their presence anywhere should not be regarded as not obnoxious. Regarding their presence in the stomach a few authors mention having observed them in the chyme, but only Einhorn (MEDICAL RECORD, June 16, 1900) attaches importance to the presence of mold and expresses himself very reservedly. My own experience leads me to accept that sufferers from this cause, excessive mold in the stomach, are very many in number.

Macroscopically, mold can be recognized as yellowish green, grass green or dark red clusters, patches, or streaks. Depending on the quantity of the mold present in the chyme, this may get its color. The yellowish green color is mistaken for bile and the dark red streaks for blood. Einhorn describes the mold he found as of blackish gray and of brownish green color. I have recently aspirated the fasting stomach of a woman, six months pregnant, and obtained about 70 c.c. of contents which would surely pass muster—macroscopically—for a hemorrhage; it was mold of the dark red variety. This experience should certainly warn us to accept the statement of any patient of having vomited blood or gall with a little reserve. There is no doubt in my mind but that greenish yellow contents have been seen by all who pay any attention to the stomach examination, but so striking is the resemblance to bile that even as great an authority as Riegel says in his book that the admixture of bile to the stomach contents can be recognized macroscopically, and that the chemical test for bile is superfluous. After having recognized the characteristics and identity of mold, I have applied Gmelin's and Pettenkoffer's test a few times with negative results.

Under the microscope the picture varies with the variety of the fungus. Undoubtedly, the mold seen by others has been misinterpreted. Patches of irregular shape and form, clusters of spores or mycelium have been explained to me as being detritus. Single asci are mistaken for isolated nuclei. At one time I thought I found crystals in the chyme—and the presence of crystals has been mentioned by some—but I have since learned that those supposed crystals are only single detached segments of mold filaments, especially of the penicillium glaucum. The young mold filaments contain no granules, but consist only of a wall membrane and are segmented at regular intervals. A single segment detached looks like a crystal. Spores are plentiful and, as a rule, are mistaken for micrococci. Until I had studied the growth and the development of several mold varieties in pure cultures, I made the same mistakes. How much of an importance this study may bear upon the interpretation of the causes of disease only the future may develop. I have found a mold variety which grew in a solution of tartaric acid (0.6 gm. in 100 c.c. dist. water); parts of this mold resemble the diptheria bacillus. Another mold variety, I believe it was the oidium albicans, had vibriones; in other molds I have seen structures that surely looked as the comma bacillus. All such structures, looking like bacilli and cocci, for which they are taken, can be seen in the chyme. Long bacilli, short bacilli, thin bacilli, thick bacilli, straight bacilli, curved and corkscrew-shaped bacilli, homogeneous bacilli and bacilli looking like a peapod filled with peas, or, if somewhat thinner, looking like a string of beads, clusters of spores looking like staphylococci, they all are to be seen in the chyme of gastrosia fungosa as phases of mold varieties. Twice or three times have I seen circular bodies about one-quarter of an inch in diameter (Baush and Lomb 1/8 objective and No. 2 eyepiece) filled with very fine granules. These granules were in very rapid motion, resembling very much the twinkling of a star. Several times have I seen circular bodies, also 1/4 inch in diameter, of which nothing but a double cell wall could be seen. Von Jaksch describes such colorless rings as the remnants of red cells. I doubt, however, this explanation.

The mold varieties which I have most often found are the penicillium glaucum, oidium albicans, and the aspergillus group. Spores are often so thickly set that nothing definite can be made out; they look like shapeless, formless, and structureless blotches; very often even their color defies description. We see dark patches without being able to give either definite structure or definite color. Some cylindrical sections are very thin, with or without granules, others are wide. Such cylindrical sections may show longitudinal or cross or oblique markings, usually of a light green color. Very often such so-called bacilli are either only or best seen after staining and decolorizing. For staining I use a solution of fuchsin (50 mg. to 75 c.c. dist. water). After staining, the specimen is decolorized with the decinormal solution of caustic soda. In some cases these bacteria (?) appear only after the decolorization. For the microscopical examination I use only the drop or two which collect at the bottom of the beaker after the chyme has been poured out of it. A drop is taken with the pipette, placed on a slide, covered with a cover-glass and examined under the microscope, unstained. Then, without removing the slide, a drop of the fuchsin solution is placed near the edge of the cover-glass. Soon the fuchsin reaches the margin of the cover-glass, and then gradually stains the specimen. The entire process of staining can be watched under the miscroscope. Then the specimen is decolorized with a drop or two of the soda solution, the soda solution likewise being placed near the edge of the cover-glass. Any excess of either stain or soda can be carefully removed with blotting paper. The soda solution, as a rule, decolorizes every thing but mold and yeast.

Succinic acid and mold go hand in hand. Whenever I found large quantities of mold I also got the reaction for this acid. But this need not be taken to infer that succinic acid is the only one that is characteristic of all mold varieties. My intention, as yet, is only to call attention to the fact that there is mold vegetation in the stomach under certain conditions, and that this mold produces injurious effects. The mold varieties which I have most often found give the reaction for succinic acid. The qualitative test (fully described in *American Medicine*, March 22, 1902) is: 1 c.c. of filtered chyme is extracted in a Straus' separatory funnel with 4 c.c. of ether and the clear ether extract is floated on a solution of ferric chlorid (one drop of a 10 per cent. ferric chlorid to 2 c.c. dist. water in a narrow test tube). At the line of junction of the two clear and colorless fluids there is a dark mahagony red ring. This test has proven a very delicate one, and is made in about a minute or two.

Plentiful as is the literature on the presence of mold in the body, but few noted it in the stomach, and of these few only Einhorn (cited above) guardedly and tentatively speaks of the necessary relation and of the interdependence between mold and certain symptoms. He says: "It is scarcely conceivable that such a mold coating of certain zones of the gastric mucosa can be unattended with disturbances of the functions of the organ. Conditions of irritation as well as inflammatory processes might be expected *a priori* from the mechanical action of the mold," and further he says, "yet it cannot be said with certainty that the mold produced the existing pathological processes in the stomach . . . it appears plausible that these mold fungi are connected to a certain extent with the above-mentioned abnormal conditions; and even if they are not the cause of these, they undoubtedly increase their severity." Such guarded assertions bespeak the true observer. In fact, I did not know how to help myself either when I first observed mold accompanying the symptoms to be described later. I wished I had known of Einhorn's article at that time instead of seeing it only lately. I found the presence of mold. I found certain symptoms accompany the presence of large quantities of mold. I was pretty sure there was an intimate connection between the mold and the symptoms given by the patient, but to definitely bring mold and the symptoms into the relation of cause and effect was something I could not do until after the lapse of a few months when I learned the chemistry of some of the mold varieties. Learning the chemistry of mold and consequently being able to demonstrate, experimenting with the growth of mold and its action, finding out experimentally what agents would enhance the growth and then applying the knowledge thus gained to abundant clinical material—all this I believe permits me to hold mold as the culpable agent which produces diseases of the stomach.

Etiology.—Sufficient has already been said on the cause of gastrosia fungosa—the presence of developing, growing mold in the stomach. What is yet to be answered is: How does mold get into the stomach? What favors its development there? Undoubtedly the most frequent media to transmit mold into the stomach are food and drink. Mold is ingested either involuntarily or, even, voluntarily, as is the case with certain varieties of cheese. Any and every article of food may have mold in microscopic quantity: Vegetables, fruits, meats, breadstuffs, dairy articles, etc. Very often we can discern the presence of mold by the sense of smell even if we cannot see any. To produce symptoms, mold must be present in the stomach in an active, living, and multiplying condition. The ingestion alone is not sufficient. Mold or its spores must remain in the stomach beyond the normal time of stomach digestion, and must find suitable surroundings in which to develop. Both these conditions must be present to effect the growing of mold. There is every reason to accept as fact that mold remains in the stomach for a sufficiently long time to develop and that it does develop there. This can be proven by the following fact: Mold is aspirated from the stomach in large clusters. But as mold was not ingested in that condition the aspirated mold colonies must needs have developed in the stomach. But since the growing of the mold from the microscopic quantities ingested to large clusters requires much more time than the ingested material remains in the stomach the ingested microscopical quantities of mold must have remained all that while in the stomach. Einhorn says (cited above): "any considerable growth of mold would be possible only if a colony of the fungi had infested a fold of the surface of the gastric mucous membrane and had become so firmly adherent that they were not carried along with the onward passage of the chyme." This explanation is highly reasonable, and I believe it to be true. But this would explain only one thing; namely, that the fungi do stay in the stomach for days and get time to develop, so that they can be seen in the aspirated chyme, macroscopically, as clusters and patches of considerable size. The answer to the second question, what conditions are favorable to the development of fungi, would be that different fungi require different media. The fungi I have so far found in the chyme seem to require saccharine media, and, as a matter of fact, I believe to have noticed, quite often, increased saccharification in moldy chyme. But saccharification is not the function of the stomach. The question would now come up: Do we have increased diastatic action; do we have diminished production of HCl; do we have delayed pouring out of HCl; or do we have all these conditions combined? I have seen all these conditions present in the stomach in cases of gastrosia fungosa. I have seen cases of gastrosia fungosa where the free HCl was as high as 30, and have seen other cases where the amount of free organic acids was, indeed, very small. But in the first cases the titration for organic acids gave very high values, and in the second cases there was either very little or no free HCl at all. Given the same amount of HCl and of organic acids, the severity of the symptoms will depend on the presence and quantity of saccharine matter in the stomach, immaterial whether the saccharine matter has been introduced as such or whether it is the product of diastatic action. So that, based upon experimental and clinical experience, I can say that the fungus growth is very much influenced by the saccharine matter in the chyme—the greater the quantity of saccharine material the better the growth of most fungi. The readiness with which mold grows on sweet media or starchy matter is pretty well known.

Symptoms.—The symptoms of gastrosia fungosa can be summed up under the heading of the presence of irritating organic acids in the stomach. The symptoms will vary with the quantity and the degree of concentration of the organic acids. The symptoms will radiate from the stomach, up or down in accordance with the spreading of the noxious acid in either or both directions. The patient will interpret the irritation in accordance with the severity of such irritation. In the milder cases, when there is yet enough of HCl, the irritation is interpreted as hunger, or increased appetite; the patient always wants to eat; the patient has a sickly gnawing sensation in the stomach, and the German well expresses this sensation as "Herznagen." This is a false appetite that must be suppressed by the physician. The symptoms may also vary from simple uneasiness and rawness in the epigastric region to severe pain and cramps. In uncomplicated gastrosia fungosa the patient does not complain of heaviness or of a load, or weight, or fulness in the stomach. Most often the pylorus is the part affected, and the reason for this is very easily explained. It is due chiefly to gravitation. The chyme and the irritating acids gravitate toward the most dependent portion of the stomach, which, most often, is the pars pylorica. The irritation of this part elicits pain and causes contraction of the pylorus. In violent cases there are cramps in the pyloric region, pylorospasmus, which quite often is mistaken for gallstone colic, and in one case I have seen such a case operated with negative results as to the finding of any gallbladder trouble. Occasionally we may feel the contracted pylorus. I have several times succeeded in feeling the pylorus in the following way: The stomach is distended with CO_2 by giving the patient half a teaspoonful each of tartaric acid and bicarbonate of soda, each in a little water. This causes slight distension of the stomach. If we now run our fingers along the greater curvature toward the pylorus, we can feel the pylorus in suitable cases. The patient may complain of no more than a raw sensation, or, again, it may be excruciating pain, spasms and violent cramps. Between these extremes there may be suffering of different gradation. The time when these pains either appear or are augmented in violence differs with the individual patient. The pains always appear either before or after meals. When they have assumed the character of cramps the pain comes after meals. But when the suffering is in a less degree, when there is only a slightly painful sensation, this is very often relieved for a short while by the ingestion of some food. This phenomenon is to be explained by the fact that the slight irritation of the mucosa by the organic acid gives the sensation of hunger, and after the ingestion of some food the consequent pouring out of HCl decomposes, dissociates the noxious organic acid, which is evidenced, clinically, by the cessation of the symptoms for a short while.

How soon after the meals do these pains appear? This depends upon the presence or absence of HCl, upon the quantity of HCl secreted by the stomach, and upon the time when such HCl appears in the stomach. The sooner the HCl is secreted and the greater is its quantity, the later will the symptoms of gastrosia fungosa manifest themselves. The location of the pain is not always limited to the stomach itself, but will spread with the spreading of the organic acid. With whatever organs these acids come in contact, irritation of such organs, with consequent pain, will be the result. Only too often the œsophagus shares the misery with the stomach, and the patient then complains of either pain between the shoulder blades, if the posterior wall of the œsophagus is attacked; or of a raw pain behind and along the sternum, if the anterior œsophageal wall is attacked or of both. The response of mucous membranes to irritation is the producing of contraction of the muscular fibers of the organ to which they belong. This contraction is, in severity, in direct proportion to the vehemence and the degree of irritation; the greater the offending material, the more sudden and the more violent the muscular contraction. Thus cardio- and pylorospasmus will be the response. The sudden and vehement contraction of the muscular coats of these orifices will be the answer to great irritation of these parts by the organic acids. The patient complains of severe cramps in the neighborhood of the umbilicus, in pylorospasmus, and of spastic, cramplike pain in the neighborhood of the ninth dorsal vertebra on the left side, if it is cardiospasmus. The volatile organic acids reach also the œsophagus and cause irritation there, with consequent muscular contraction. Especially is this contraction marked at the beginning of the œsophagus. The patient points to the suprasternal notch and describes his sensation as that of choking, which we have learned to describe, unfortunately, as the globus hystericus. There are no hysterics about this, it is actual fact. In those cases where there is a sufficient amount of HCl, together with the organic acid, the patient experiences the sensation of hunger; he has a good appetite, nay even a ravenous appetite, and very frequently such patient boasts of such an excellent appetite that he feels as if he could eat up a horse. And it is really a surprise to such a patient why, with such a good appetite, there should be suffering, pain, and distress in the stomach. This is a false appetite, which it is the duty of the physician to suppress. Great, indeed, must be our persuasive powers to convince the patients of the danger of such an appetite, even after they have been relieved of their distressing symptoms.

The symptoms of dryness and thirst are next in importance. In aggravated cases the patient can hardly alleviate his thirst; he drinks all the time, thus introducing large quantities of water into the system. From this excessive amount of water the system rids itself by the natural channels of perspiration and micturition, giving these symptoms. Thus we get intense thirst and polyuria—what a vivid clinical picture of diabetes! Should such symptoms, by chance, be associated with alimentary glycosuria, and a diagnosis of a case of confirmed diabetes will not be doubted. I have recently had such a case in a woman, about middle age, who had been treated for a few months for diabetes just because of these two symptoms: Intense thirst and polyuria, although there was no sugar in the urine. The intensity of these two symptoms, which hindered that woman greatly in her butcher business, evidently prevailed on her physician to make the diagnosis of diabetes and to treat her for it with nearly disastrous result. This woman made an excellent recovery, gaining weight and color in about four weeks. In the course of time the irritation will naturally spread from the stomach to the œsophagus, from the œsophagus to the pharynx, and from the pharynx to other parts with which this is in communication. Vomiting is very often a distressing symptom. The patient may vomit either a green or a dark red fluid, and say that he vomits bile or blood, as the case may be. This vomiting occurs chiefly either at night or early in the morning when the stomach is yet fasting. The vomiting is due to the great irritation of the stomach by the large amount of the organic acid, which causes spastic contraction of the stomach, expelling its contents.

To sum up—the symptoms of gastrosia fungosa are: Heartburn, rawness or pain, spasms or cramps, in the region of the pylorus and posteriorly on the left side at about the ninth dorsal vertebra, burning sensation in the epigastrium, rawness and burning behind and along the sternum and between the shoulder blades, a choking sensation, dryness in the throat, thirst, polyuria, excessive perspiration, sour taste, regurgitation of sour masses, vomiting and, as a rule, headache, which is most often of the frontal type.

Diagnosis.—The clinical symptoms must be corroborated by an examination of Ewald's test meal, which must invariably be preceded by an examination of the fasting stomach. In the examination of aspirated chyme of the test meal we may arrive at important deductions by the proper observation of the physical appearance of the aspirated contents. The quantity obtained from the stomach, the character of the chyme with reference to the fineness of subdivision of the solid part, the color of the fluid portion, and the odor of the aspirated ingesta, they all have their own and important interpretation. Properly appreciated, the very physical appearance of the chyme will very often make the diagnosis. The quantity, as a rule, is quite considerable, especially at the beginning of the disease. The solid part of the chyme is very fine, almost always appearing as if the chyme consisted of a "floury" layer at the bottom, with fluid above it; this after the chyme has stood quiet for a little while. The color of the fluid part is of a greenish hue, very often of a decided green. The odor is pungent, sweet sour, often resembling the odor of raisin wine. This condition has been seen and described, but invariably has been misinterpreted. This characteristic physical appearance has been associated with atony of the stomach, the diagnostic criterion being accepted to be the large quantity of aspirated chyme. But far from being atony of the stomach, such a condition must be looked upon as characteristic of hypertony of the stomach. It only depends upon the proper understanding of the cause for the large quantity of the aspirated chyme. The fact that a large quantity is aspirated does not necessarily imply that the muscularis ventriculi is unable to expedite matters by reason of its being weak. The fact that a person does not get out of a house does not necessarily mean that that person never made the effort to get out. He may have tried very hard to release himself, but the door may have been locked. The same explanation is due in this disease. The large quantity of chyme we aspirate is not due to the fact that the stomach is atonic, but that the door, the pylorus, is locked. The flour-like appearance of the solid part of the chyme, the "floury layer," attests that the stomach has made very great efforts to rid itself of its contents, but that the pylorus was spasmodically contracted. And the reason why the pylorus so contracts is that it is too strongly irritated by the organic acids within the stomach. We know that the stomach orifices close during digestion, this closing being due to irritation of the mucous membrane. The greater the irritation, the stronger, the more prolonged is the closure of the pylorus. That the chyme is highly acid in those cases has been noted by every one, and it is this highly acid chyme which strongly irritates the pyloric mucosa. The condition that prevails is: The pylorus is closed and the gastric mucosa endeavors to expel its contents. The greater the irritation, the stronger and the more prolonged the closure of the pylorus and the stronger are the efforts of the muscularis. Between these two conditions, spastic contraction of the pylorus and increased efforts of the muscularis, the inclosed chyme is very finely macerated, giving the "floury layer." A large quantity of chyme, the solid part of which is flour-like in appearance should be recognized as a condition of hypertony due to stenosis of the pylorus, "stenosis pylori ab irritatione." This view is more fully explained in my article in the *Philadelphia Medical Journal*, May 24, 1902, which was accepted for publication last December. On March 6 of this year appeared in the *Deutsche medizinische Wochenschrift* an article by J. Boas of Berlin, "Über Magensteifung, on Stiffening of the Stomach," in which that eminent author likewise questions the now-accepted theory of atony of the stomach and comes to the same conclusion as myself. This phenomenon, stiffening of the stomach, I elicited every time I thought of it, after reading the article, in my cases of organacidia gastrica. Boas' ideas of the tonicity of the stomach, as at present understood, are well expressed in the very first sentence of his article; he says: "The knowledge of the motor function of the stomach and of the interference with this by disease is yet very dark . . . what is being taught of it (muscular action of the stomach) is full of gaps and controversies." Further, he says: "In my experience of the last few years I have found the tonic contraction of the fundus relatively very frequently." He also expresses his doubts as to the correctness of the diagnosis of atony of the stomach when based on dyspeptic symptoms accompanying the prolonged staying of chyme in the stomach, and says: "As is known, we have heretofore designated as atony of the stomach all such cases that gave subjective symptoms of dyspepsia and which gave objective evidence of prolonged retention of the ingesta. Already before my attention was called to the fact that very often such atonies were seen in such individuals whose history pointed to the existence of an ulcus." He then cites the case of a physician whose stomach he examined after a test breakfast and found as follows: Test breakfast *well* chymified; free HCl 66 (he does not state which indicator he used), stomach contents (Mathieu and Remond), 340. And then he continues: "This examination shows every sign of 'atony of the stomach,' and yet a simple primary weakening of the stomach cannot be assumed in view of the repeated elicitation of the stiffening of the stomach. It doubtless is a case of a slight cicatricial *stenosis of the pylorus*." He thus positively denies the diagnosis of atony in this case, notwithstanding the large quantity of aspirated chyme, and makes the correct diagnosis of stenosis pylori. Further, he says: "The question is only what is the cause of the stenosis, the assumption of a so-called atonic ectasy, of continuing hypersecretion, etc., should be disregarded."

The green color of such chyme is due to the presence of large quantities of mold. The pungent sweet odor has for its cause the presence of the organic acid—succinic acid—with which is usually associated an increased saccharification. Of course, such physical appearance is present only in uncomplicated cases; complications will cause modifications.

To fully observe the physical appearance the aspirated chyme should be left standing still for about ten minutes, so that the solid part may have time to settle. After this we proceed to the microscopical and chemical examinations, previous to which the chyme is filtered. For the microscopical examination a drop of the residue remaining on the beaker, after its contents have been poured out on the filter, is taken with a pipette. This drop is placed on a clean slide, covered with a thin cover-glass and put on the stage of the microscope. We first examine the specimen unstained and then stain in the manner described above. Mold will be seen in many varieties and shapes. It may be seen in patches of irregular shape and constructure, green ish yellow or orange yellow in color, irregularly shaped patches of an uncertain dark color, now deep red brown, and again very dark orange or a very dark purple; there may be some other colors. Mold is seen as very fine pencils, especially noticeable after staining. Single segments of mold look, to all appearances, as crystals. Mold is seen as bacilli of various structure, thickness, and lengths, according to the variety of the special mold species; clusters of spores may be taken for staphylococci. The specimen is now stained and decolorized, as described before, and again examined. Very often a certain bacillus, resembling very much the tubercle bacillus, is seen after the decolorization. The more I study mold, the more I begin to doubt the identity of bacterial entities. The conviction seems to force itself upon me that what we recognize as bacteria are seemingly but parts and phases of mold. However, prudence would dictate great reserve in making any such allegations authoritatively. Indeed, it is the easiest thing to study mold. All we need is a fairly good microscope—an immersion lense is not an absolute necessity, the mold comes of itself.

For a complete chemical analysis both a qualitative and a quantitative analysis are of importance. The qualitative test for organic acid is made by extracting the chyme with ether and floating the clear ether extract on a weak solution of ferric chlorid, as described fully in my article ("Some New Facts in the Chemistry of the Stomach," *American Medicine*, March 22, 1902). For that purpose 1 c.c. of chyme is extracted with 4 c.c. of ether in a separatory funnel. The chyme and ether are well shaken up, then the clear ether extract is floated on the iron solution. This consists of one drop of 10 per cent. ferric chlorid to 2 c.c. dist. water, in a narrow test tube. At the junction of the iron solution with the ether extract a red brown ring will show the presence of succinic acid. The quantitative analysis is made in the usual way by titrating with a decinormal solution of caustic soda, using as indicators: (1) A super saturated alcoholic solution of tropæolin 00, for the determination of the free HCl; (2) A half per cent. solution of dimethylamidoazobenzol as an indicator for the free organic acids, and (3) A one-per-cent. solution of phenolphthalein for the determination of the general acidity. To 5 c.c. of the filtered chyme are added two drops of the tropæolin solution. A cherry-red color will result in the presence of free HCl. In the absence of free HCl the chyme becomes amber-colored. We now add slowly the sodium hydrate from the burette until the cherry red color has changed into an amber color. This is the end reaction. Now two drops of the dimethyl are added. In the presence of organic acids the now amber-colored chyme turns carmine red. The titration is resumed and continued until the carmine red turns into a lemon-yellow color, which signifies the approximate end reaction of the organic acids. Again are added two drops of the phenolphthalein and again titrated until the yellow-lemon color has turned red. Only 5 c.c. are needed for the whole determination. Care should be taken not to overtitrate. To the beginner, the first titration will cause some difficulty until his eye becomes acquainted with the color of the end reaction of the tropæolin. To do this I would advise to add the tropæolin to a chyme, known to have no free HCl (to be ascertained by Günzburg's reagent), and learn the exact color. A narrow column shows the color better than when the contents are in a wide beaker. Therefore, when there is a doubt as to whether or not the amber color has been reached some of the contents from the beaker may be poured out into a narrow test tube to show the exact color. Günzburg's reagent gives a ready means to control the tropæolin index. If, for instance, the tropæolin titration gave an index of, say, 20 free HCl, and we would like to verify that, we take another 5 c.c. of filtered chyme and add, say, 0.9 c.c. sodium hydrate. This would be an equivalent to an acidity of 18. After such addition we test with Günzburg, which should still give a positive result. After this we add NaHO, say another 0.3, and again test with Günzburg, which then should give a negative result. To calculate the acidities note the burette reading before we begin to titrate and at the end of each titration. If 5 c.c. of chyme are used and the burette reads 2.3 before the beginning of the titration, 3.2 at the end of the tropæolin titration, 4.8 at the end of the dimethyl titration and 5.7 at the end of the phenolphthalein titration the calculation will be: Free HCl, 18; organic acids, 32; general acidity, 68; 5 c.c. being the twentieth part of one hundred we multiply the number of c.c. of the NaHO used in each titration by twenty.

Prognosis.—In uncomplicated cases the prognosis is good. A cure can be positively assured. The cases I have had have been cured within six to eight weeks. From the history of most of my cases I could judge that the disease had lasted for several years. In complicated cases the cure will depend upon the nature of the complication.

Sequelæ.—The spastic contraction of the pylorus and the contracting stomach throwing the chyme toward the pylorus will soon be followed by the necessary consequences, viz., inflammation of the pyloric region. The frequency of this disease—gastrosia fungosa—and the fact that at autopsies it is the pyloric region which is mostly found affected, seem to throw the necessary light upon my conclusions. It is only a question of time when the pylorus will cease to respond, will no longer close, and thus create the condition of "insufficientia pylori." That oft-repeated and prolonged spastic contraction of the stomach and its orifices will interfere with the blood circulation is not a matter of deep speculation, and varicose veins in the stomach are surely not a rarity. But let it not be understood that gastrosia fungosa is the only cause of varicose veins in the stomach. Once this condition is established, the bursting of such varicose veins, by whatever cause—straining or otherwise—need surprise no one. Are we not led now to the understanding of the origin of hemorrhagic erosions upon which Virchow (in a discussion on hemorrhagic erosions by Pariser at the Berliner medicinische Gesellschaft, some time in the spring of 1900, and at which I was present can look in no other light than as being ulcers? Indeed, it requires no vivid imagination to reason further. That the stomach under such continuing conditions will not remain the only affected organ is only too evident. The regurgitation of sour acrid matter will not fail in producing deleteriou effects, in due time, upon such organs with which such irritating matter comes in contact, whether i be the œsophagus alone or parts beyond it. Thi latter condition suggests itself as especially virulen in infant and child life, which by no means make exception to be affected with gastrosia fungosa Pertaining to child life, I might mention but on affection which causes a great deal of anxiety laryngismus stridulus. But the evil influence this disease is not confined to spreading only upward; the intestines get there share in due time.

Treatment.—The treatment can be discussed under three headings: (1) Dietetic; (2) Mechanica and (3) Medicinal. Under the first heading belongs, first to avoid eating mold, and second to avoi

ıting any food varieties favorable to the develop-
ıent and growth of mold. With but few exceptions
ıold, macroscopically visible, is repugnant, and is
voided. Food articles with a musty, moldy odor
ıould likewise be refused. Some varieties of cheese.
rized for their sharp, piquant taste, which taste
due to the presence of mold, should not be per-
ıitted to be sold. A normally functionating stom-
ch is in no need of such an appetizer. When a
esire for a stomach excitant is present, such
omach should be carefully examined. No food is
xempt from moldiness, but sweet foodstuffs show
reater and readier proneness to mold growth.
weet fruits, especially grapes are great harbors of
ıold, and the latter should never be eaten by any-
ne unless they are thoroughly washed in running
ater before eating. Vegetables intended to be eaten
ncooked should be well cleaned, the outer leaves
moved, and thoroughly washed in running water.
eak organic acids do not destroy the growth of
ıold; one must have this in mind in thinking of
ılads. The food should be cooked and eaten soon
ter. No family should cook more than is re-
uired for the next meal and destroy whatever is
ft, as cooking the food does not prevent the
ccess and development of mold after such food
as been cooked. The poor patient especially
ıould be warned not to eat any food left over from
ıe day before. Very often they eat food left over
r several days, and then pay for such infraction
ı the laws of hygiene with severe attacks of "in-
igestion." Meat must likewise be thoroughly
eaned and washed before cooking. The orthodox
wish custom of making the meat "Kosher"
ıould be universally adopted. This consists in
st soaking the meat in plenty of clean water for
out twenty minutes and then salting it thoroughly.
fter the salting the meat is put on a sieve-like tray,
as to permit free drainage. For about thirty
ıinutes the meat is left in the salt, after which it is
ain thoroughly washed in clean water, to remove
ıe excess of salt. Then only is the meat ready for
oiling, stewing, etc. Meat for broiling purposes
ed not undergo this process. The meat does not
ıffer by the "kosher-making." I might cite here
y own personal experience. For a long while I
as dissatisfied with the meat I got at my table.
oiled. stewed or fried, it always had the same
oldy, musty odor. The butchers were frequently
ıanged, without avail. But after I thought I had
scovered the cause and ordered the meat treated
rictly in accordance with the orthodox Jewish
ws, I had no more trouble with the meat, no mat-
r where it was purchased.

Sweets, sweet fruit, stewed fruit, jams, and pies
ould not be allowed. Nothing sour should be per-
itted, as the stomach already suffers from the
esence of organic acids; very often the patients
mplain that they feel worse after eating sweets.

The mechanical treatment consists in cleaning
t the stomach from any fungi. This is best done
lavage. Indeed, this disease offers the ideal
dication for lavage of the stomach. The water
distending the stomach obliterates any folds,
ıd washes away the mold growth lying between
ch mucous folds. The stomach should be washed
ther before going to bed or before breakfast, pre-
rably the first. At all events lavage should be
ne on an empty stomach, as we surely do not care
rob the patient of the benefit of his meal.

Medicinal treatment.—The first thing that will re-
ıire our attention is the heartburn. Knowing that
is a sour taste and sour eructation that causes the
isery, it is but natural to prescribe the time-
nored bicarbonate of soda. But the failures of the bicarbonate to come up to the expectation are very many indeed. The patient may or may not feel relieved by the bicarbonate. In the latter case, if the patient comes back, the physician is surprised by the failure of the alkali to act as desired. In fact, such instances are numerous enough, if not the rule. The organic acids in the stomach do not require neutralization but chemical decomposition. The bicarbonate neutralizes what HCl there may be along with the organic acid, and in presence of the now introduced alkali the diastatic action proceeds, with the further production of organic acids (experiment). This explains why there may be some relief for a little while in some cases after the alkali and why the pains soon after reappear. Instead of giving sodium bicarbonate I give, with excellent results, the mineral acids. I usually give the HCl at meals and a mixture of equal parts of sulphuric and phosphoric acids ten to twenty minutes after meals, according to existing conditions—fifteen drops of this acid mixture in a glassful of water, which is preferably warm. These inorganic acids decompose the organic acids, destroying their action, and do not give the favorable medium for further development of the organic acids. The dilute nitric acid is also very good, but it must be watched, and the appearance of headaches was to me an indication to discontinue its use. Some patients seemed to require Fowler's solution after they had first been benefited by the mineral acids. This, together with the dietetic and mechanical treatment, would constitute all the therapy for an uncomplicated case of gastrosia fungosa. Where there are complications these will have to be taken into account.

Zymosis Gastrica (*Ζύμη*, yeast).—Next in frequency is zymosis gastrica. This pathologico-chemical disease of the stomach is due to the presence of yeast cells in their budding, sporulating, multiplying condition. This condition can be brought about by repeated ingestion of large quantities of yeast-containing food and drink, by the diminution of the quantity of HCl, or by the delayed secretion of the HCl.

The symptoms of this disease are caused by the physical and chemical properties of the yeast. The development of CO_2, normal in diastatic action, is much enhanced by the presence of yeast (experiment). So that in the presence of yeast the amount of CO_2 production will be much increased with the consequent distention of the stomach. The absence of the HCl, and the presence of an alkaline medium favor the growth and the development of yeast (experiment). The symptoms of stomach distention will vary from a slight heaviness to an unbearable sensation of oppression; the patients have to loosen their trousers, corsets, or skirts, as the case may be. The mechanical effect of the distended organ, encroaching upon the functions of the neighboring organs gives symptoms. The heart's action is interfered; its physiological excursions are limited, and the patient complains of palpitation. Excessive distension with gas may be of very grave and possibly of fatal result. The recent experiments by A. Oppenheim (*Deutsche medinische Wochenschrift*, March 27, 1902, Beitrag zur Bekämpfung des Meteorismus) show that the distention of the colon displaced the heart altogether, and that it may also produce death. We surely could reason the same to happen when the stomach is excessively distended. The largely-distended stomach interferes also with the physiological action of the lungs, and the lungs expanding upon the distended stomach, compresses the circumference of the stomach, which is evidenced as pain on respiration. In its efforts to get out the CO_2 produces belching when it leaves by the cardiac opening and gurgling when it escapes through the pylorus. Bitter taste is its chief accompaniment. In more aggravated cases there is nausea and vomiting, due to the production of that highly nauseating, penetrating, and irritating acid, butyric acid, which is a constituent of yeast. As in the former disease, headaches are very often present.

The clinical diagnosis will be aided by inspection and percussion. Inspection may show a bulging in the gastric region, the size of which depending on the degree of the distention of the stomach. Epigastric pulsation may at once attract our attention. This is due to the cardiac impulses being transmitted to the skin over the stomach by the distended stomach, which for such purpose forms a practically solid body for the transmission of the apex beat. Percussion will elicit tympanitic resonance.

The physical appearance of the chyme resembles much that of the preceding disease. Here likewise we aspirate a large quantity, which separates into a "floury layer" at the bottom with fluid above. The cause for this is the same as in gastrosia fungosa, stenosis pylori ab irritatione. The odor is much more intense than in gastrosia fungosa; it is very irritating and pungent, due to the butyric and acetic acids. In severer cases the chyme will separate on standing into three layers, fluid between two solid layers. The top one is the layer specifically lighter, because of the gas contained within it; gas bubbles are seen to rise from this layer.

Microscopically, the diagnosis will be made by seeing large numbers of yeast chains and large quantities of budding yeast. Normally, yeast is present in the stomach only as single isolated cells, or occurs possibly in twos, each cell being of about equal size. A chyme that contains budding yeast or yeast chains is not normal. Of this I have ample evidence and proof. In zymosis gastrica the yeast occurs either in chains or we can distinctly see mother and daughter cells. Yeast is seen in the process of division, forming figures of eight, others become elongated in their further metamorphoses. In one case I have aspirated some contents, which, under the microscope, showed nothing else than to consist of a pure culture of budding, sporulating yeast and yeast in chains. Bacilli are seen of various shapes and sizes, much more than in the preceding disease. In this condition of the stomach the yeast cells are also seen in the process of chemical evolution into other cells—acetic and butyric acid cells.

The chemical test will be for acetic and butyric acids, described in my article in the MEDICAL RECORD, November 16, 1901. The qualitative test for these acids is made in the same way as in the preceding disease, that is, the floating test. The ring that appears between the ether column and the iron solution is very similar in color to that obtained in testing for succinic acid. But whilst succinic acid gives the characteristic ring in even very weak solutions butyric acid solutions must be quite concentrated to give such ring. Whenever butyric acid is present in a large enough quantity to give the dark brown ring the identity of the brown ring must be established. This is done as follows: After completing the floating test as much of 95 per cent. of alcohol is added to the test tube as ether extract was floated, or rather a little less, and the test tube then inverted two or three times. The ether column, which was clear before, turns an orange color. The quantitative analysis for these acids does not differ from the quantitative analysis for succinic acid, described.

The prognosis in this disease, when uncomplicated and not yet far advanced, is even more favorabl than in gastrosia fungosa. But the sequelæ I believe, theoretically, to be much graver.

The treatment consists of the same elements a that of the preceding disease; dietetic, mechanical and medicinal. The dietetic treatment means excluding from the diet all articles which contai yeast. As it is the CO_2 produced by the yeast tha causes symptoms, all food and drink containing CO_2 or which cause and favor its production must b eliminated from the diet. Thus must be exclude breadstuffs, into the making of which yeast enter as a factor. Especially should the crust of the brea be excluded, as several of my experiments prove that almost all of the yeast was in the crust. Wh there should be a ban upon fresh bread I do no know. Surely we should not permit any stale bread stale bread is lighter through the loss of water b evaporation, but it is much sourer, due to the development of tartaric and lactic acids; neither of thes organic acids should be welcomed to the stomac The reason that fresh bread harms, and I will adm that, is not that there is anything intrinsicall wrong with the fresh bread, but that the fresh brea is more appetizing and a much greater quantity of is eaten. It is the greater quantity, and with it th greater quantity of yeast introduced, that harm Fruits that contain yeast and are prone to fermentation, especially grapes, should be blacklisted. Sod water, seltzer, vichy, etc., must likewise be avoide If bread must be given, only a little of the soft pa may be allowed. Instead of bread, crackers, biscuit or matzoth can be allowed. There is absolutel no reason why noodles, macaroni, spaghetti, potatoes should be prohibited. I always permit the —nay, I insist upon the patients eating these—ar have always met very satisfactory results. All kin of cabbages, turnips, and radishes should likewise excluded, so also raw onions. Beans and peas ca be permitted only when their external cellulose cov has been removed before cooking. With beans can be done this way: the beans are soaked ov night in water. In the morning the shells will found burst, curled up, and loosened from the bea Now each bean is to be taken between the finge and the bean squeezed out of its shell. The bea thus freed from the shells can now be boiled a eaten. Of peas, only split peas can be allowe Nothing sour should be permitted, as this mea introducing into the stomach of organic aci Coffee and tea must likewise be put on the blackli My experiments with coffee (to be published some future time) have repeatedly and conclusive proven that HCl entirely disappears when broug together with an infusion or a decoction of even ve strong, *i.e.* very sour, coffee, and we might think he of a surprising paradox—an acid neutralizing acid. Of course, this not a process of neutralizati but the exact chemistry will be explained, together with my report of the research. Water and m should take the place of other beverages. Pla milk, milk and hot water, milk with a little vich milk with a little salt added, or milk with hot water added, should be administered to suit the taste of the individual. It is my opinion that fresh cows' milk will never tire. However, milk must not be allowed *ad libitum*, as large quantities of milk may likewise give rise to the formation of gases. Well-fermented light wines might be allowed in moderate quantities.

The mechanical treatment is the same as in the former disease; lavage of the stomach. Medicinally the mineral acids are to be given. Phosphoric acid is the best of any other mineral acid, but I usually combine this with the sulphuric acid in equal parts, of which fifteen drops are given in a glass of wa water, either before or about twenty minutes after the meal. The severer the symptoms, the sooner will the inorganic acids have to be given. Complications must be met.

Plentiful are the cases where there is either gastrosia fungosa or zymosis gastrica. But very often both these conditions are present at the same time. The patients will consequently give symptoms of both conditions. A very often-met symptom of organacidia is frontal headache and vertigo. Some patients say they are "dopy"—they cannot bend down at all because of getting dizzy and the "blood rushing to the head." I believe the cause of this to lie in the fact that the CO_2 which is largely developed in this condition together with the highly irritating, volatile organic acids come in direct contact with the part complained of. These acids and the gases reach the frontal cells in a most direct way. From the stomach through the œsophagus to the pharynx. Thence through the posterior nares and nose upward until they reach the frontal cells. From the pharynx there is open communication with the middle ear through the Eustachian tube. As a matter of fact, patients suffering from organacidia gastrica very often complain of buzzing and shooting in the ear; they are very often subject to nasal catarrh with its evil influence. To imagine the injury that is possible to result from the chronic irritation of the œsophagus and pharynx by the irritating, volatile acids and regurgitated, acrid acid matter on one hand and inflammation of adjacent parts resulting from continuity on the other hand, is an easy matter. The œsophagus, in the course of time, must and does suffer. Œsophagitis is recognized by the pain or burning or rawness between the shoulder blades and behind and along the sternum. Ulcer of œsophagus in organacidia I have already reported (Medical Record, March 1, 1902). The attack on the œsophagus is surely not limited to ulcer alone. The regurgitated acid matter comes easily in contact with the epiglottis and larynx, and if such a condition is often repeated, an inflammatory condition of both these structures cannot very well escape. How far organacidia gastrica operates in child life to produce laryngismus and other ill effects can at the present moment be only a matter of conjecture. Inflammation of the middle ear, chronic rhinitis, the inflammation of the lacrymal ducts through the continuity from the nose with consequent conjunctivitis and the sequelæ of this, are all easily understood when the chronic inflammatory condition of the pharynx is recognized. How much organacidia is o be blamed for inflammation of the tonsils and or the production of adenoids only concurrent observation will teach. Once the chronic inflammaory condition of the pharynx is established, and the nflammation of this organ has spread to contiguous structures, produeing, chronic rhinitis, with blockng up the nasal air passages, a circulus vitiosus is fully established. We have then obstrucion to the breathing together with organacidia gastrica, two factors that will lead, if unchecked, to he inevitable. The influence of organacidia gasrica upon the intestines cannot very well be regarded as favorable, but I will not consider it here. For the avorable treatment of organacidia gastrica, complications must well be kept before our eyes. Especially is this the case should insufficientia pylori ccompany it. For the treatment of this disease I efer to my article in the *Philadelphia Medical ournal* of May 24, this year.

In writing this article I have omitted to mention ther symptoms which the patient complains of ccasionally, but which symptoms do not belong nmediately to the stomach, such as constipation, diarrhœa, especially morning diarrhœa, distention of the bowels, griping pain in the bowels, etc. Such are frequently concomitant symptoms, but they are engendered by organs other than the stomach.

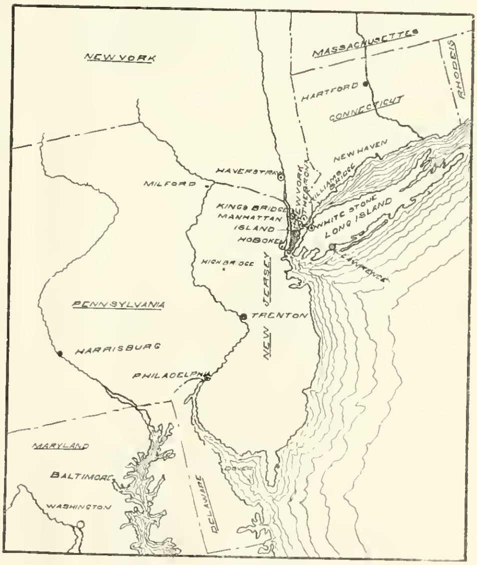
ÆSTIVO-AUTUMNAL FEVER IN MANHATTAN ISLAND AND ITS ENVIRONS.

By HENRY STUART PATTERSON, M.D.,

DEPUTY ATTENDING PHYSICIAN AND CHIEF OF MEDICAL CLINIC, HUDSON STREET HOSPITAL; CLINICAL ASSISTANT, DEPARTMENT OF MEDICINE, VANDERBILT CLINIC.

Much misunderstanding has been associated with the malarial diseases of New York in general, and with the æstivo-autumnal variety in particular. Every year Johns Hopkins graduates, who take positions on house staffs in our hospitals, express incredulity when informed that malarial fever on Manhattan Island is quite often endemic. Tertian intermittent fevers, developing in or close to New York City proper, have always been more or less common; and that this fact should be generally unknown is evidence that the clinical field is so large that observers are unable to find time in which to classify their results. As late as 1900 it was stated by eminent authority that æstivo-autumnal fevers did not belong to these latitudes, but were always brought here from southern states, if not from the tropics. In a most excellent article in the Medical and Surgical Report of the Presbyterian Hospital for 1898, Solley and Carter report two cases of æstivo-autumnal malaria; one of the patients had not been out of New York for five years, the other had been in the city for seven months. The clinical experience of the last three summers has been such that we must infer that either these cases have not been generally recognized, or something has happened that has increased a variety of infection previously extremely rare. While clinical microscopy has certainly developed to such an extent that nearly all hospital internes are capable of recognizing malarial organisms, it seems more probable that endemic cases of æstivo-autumnal fever are more common to-day than they were before the year 1898. It is the purpose of



this paper to bear witness to the fact that this variety of fever is now one of our domestic diseases, by citing cases on record at the New York Hospital, but it should be borne in mind that similar cases are on record in Bellevue and Presbyterian hospitals, if not in others.

In reviewing the cases of remittent malarial fevers on record at the New York Hospital, it is found that none is on record as occurring previous to the Spanish war in which infection was not acquired either in the southern states, the West Indies, or Central or South America. Cases in which positive blood findings were absent are not here considered.

In 1899 the first undoubted case of æstivo-autumnal fever arising near New York was observed. The patient had been living in Whitestone, Long Island, and an examination of his blood

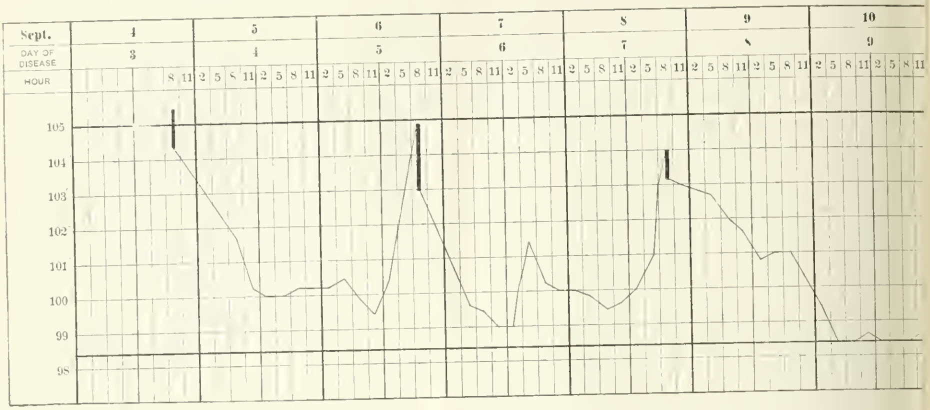


CHART 1, CASE 6188—Showing the marked elevation every other day, with remissions alternate days. The long remissions in this case led the physicians in attendance to take a diagnosis of æstivo-autumnal fever several days before organisms were found.

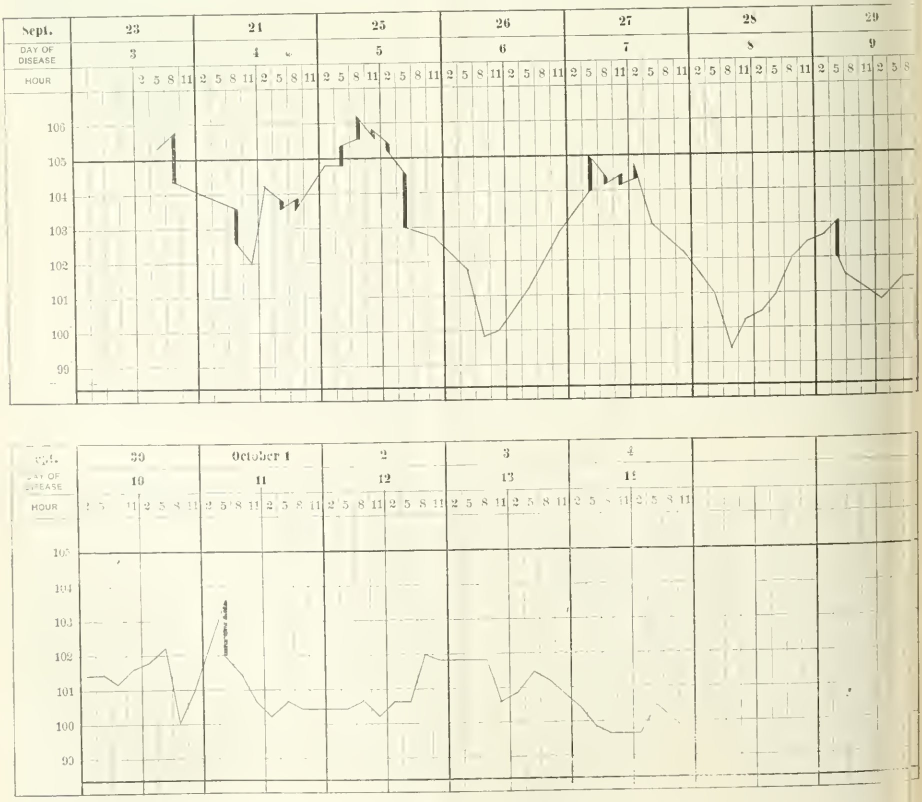

CHART 2, CASE 4489—Showing elevations and remissions alternate days, and the inefficacy of baths during the period of elevation.

revealed an unusually large number of crescents.

In 1900, the first case was that of a young man who had been living in Kingsbridge, in whose blood crescents were found. Two cases not on the records but observed about the same time, one patient living in Williamsbridge, the other in the Bronx, both showed crescents. The next case, in which the infection was traced to Lawrence, Long Island, also showed crescents. Another case is recorded in which the blood contained crescents, which originated near Philadelphia. Case 4727 is of unusual interest; in this instance crescents were found in the blood of a man who, we believe, was sincere in saying that he had not been off Manhattan Island for four years.

In 1901 a young negro, in whose blood signet rings and crescents were found, developed the disease in Haverstraw. A blood examination in the next two cases, one infected in or near Hokoken, the other on the west end of Long Island (6188—Chart No. 1), discovered the presence of crescents in one instance, a single characteristic ovoid in the other. Case 6472 developed along one of the railroads leading out of New York, at no great distance from the city, and showed young forms of æstivo-autumnal organisms.

Here there are records from one hospital alone of one case of æstivo-autumnal fever developing on Manhattan Island and ten developing within a radius of from ten to one hundred miles of New York, the geographical distribution being illustrated by the accompanying map. The sources of origin of cases 6188 and 6472 are traceable to districts and not to particular towns, so they are not presented.

The Spanish war would seem to be the period from which the more common occurrence of domestic cases of this fever dates. In the majority of our city hospitals are reliable records of cases brought from Cuba in 1898. The spring recrudescences of 1899 could well be the source of increasing infection of the anophyles in that year.

In connection with these cases, the question of diagnosis naturally arises. In a case of fever in which a palpable spleen is all that physical examination records, or in a case of fever without splenic enlargement which has been ill sufficiently long to exclude the exanthemata, the choice lies ordinarily between malarial and enteric fevers, with the theory of probabilities in favor of the latter. In cases of a negative blood finding—and in these days when typhoid bacilli are readily recovered from the blood, this method of investigation ought not to be overlooked—there are a few clinical points which seem to help. In the first run of the fever, there appears to be, in a number of the cases at least, a marked elevation in temperature every other day, with a corresponding remission alternatedays, with a gradual subsistence up to about the fourteenth day. This point is rather strikingly illustrated in cases 4489 (chart 1) and 6188 (chart 2). On hydrotherapy, the cases act in a very different manner from cases of typhoid. During the periods of elevation in temperature tubs may have very little effect on the curve; in chart 4489, for instance, the temperature one half hour after the bath on four successive occasions on the fifth day of the disease was higher than when the patient was put in the tub. The tubs may, however, precipitate remission, which the charts show to be much longer and much greater than in enteric fever, except in cases of that disease in children, when the drops in temperature after baths may be four or five degrees, or even to subnormal, but these remissions are as temporary as the less marked reactions of adults.

Unless the physician is reasonably sure that he has to deal with a case of malarial fever, the administration of quinine may create a great deal of mischief. In cases of typhoid, remissions accompanied by sweating, followed by chills and rises in temperature, may be caused by the exhibition of this drug, and much obscurity may be thrown about an otherwise clear case. Two such cases were observed in the New York Hospital in 1901 alone. They looked like cases of typhoid, their temperature resembled that of malaria, except that the chills were more frequent. One had been on steady doses of quinine, the other on an antipyretic, probably quinine. On the removal of the drug, the temperatures behaved in a perfectly straightforward manner. When the diagnosis is perfectly clear, quinine sulphate grs. 10 and arsenious acid grs. $\frac{1}{50}$ may be given every four hours until the temperature reaches 101°; and then quinine grs. 5 and arsenious acid gr. $\frac{1}{50}$ every four hours should be given until after the time for the next elevation, when such elevation is not apt to occur or is only slight. The medication is then given three times a day, and the patient allowed to get up when he has been without fever ten days. At this time the medication should be given twice daily and persisted in for two or three months, only stopping temporarily in the presence of unpleasant symptoms. Even when taken persistently for several months, and later omitted and used alternate weeks, the case which developed in Williamsbridge had a recurrence about eight months after the infection was first controlled. If the patients cannot take the drug in solution, quinine in capsules with dilute sulphuric acid minims 20 seems to be just as efficient. In pernicious cases one should not hesitate to give quinine by the needle. In the ordinary cases quinine and arsenic really seem to be much more efficient than either alone, and their action is greatly augmented by rest in bed.

It does seem that individuals are rather more frequently infected with æstivo-autumnal fever in and about New York than previously. Whether this increase in endemic cases is permanent, the next few years alone can decide.

Ventroscopy, or Illumination of the Abdominal Cavity in Vaginal Cœliotomy.—D. v. Ott has improved the technique of vaginal cœliotomies by devising a system of electrical illumination of the field of operation, combined with a modification of the Trendelenburg position. The patient is placed on the back in the usual lithotomy position, and then the pelvis is raised until the body lies almost at the angle of the Trendelenburg. When the vaginal vault is incised under these conditions air rushes into the abdomen and the intestines slip high up out of the way and leave the pelvis free, except for its own viscera. By the use of an electric forehead light, or of the author's special retractors with lamps attached, a beautiful view of the interior of the abdomen can be obtained, and by seizing the anterior abdominal wall in the neighborhood of the umbilicus with a volsella and drawing it upward the field of vision can be extended to include the cæcum, appendix, transverse colon, the stomach, a part of the liver, gallbladder, anterior abdominal wall, and spleen. Before making the change of position, the vaginal wound is covered with a tampon of absorbent cotton, to filter the air that enters the abdomen and eliminate all danger of infection from that source. By this modification the vaginal route is robbed of its most serious drawbacks, viz., the necessity of working in the dark by touch alone, and the inconvenience of having the intestine constantly forced into the field through the respiratory movements and the intraabdominal pressure.—*Centralblatt für Gynakologie.*

WHY IS MODERN SCHOOL LIFE SO OFTEN DISASTROUS TO THE SCHOLARS, ESPECIALLY TO GIRLS?

By RICHARD COLE NEWTON, M.D.,
MONTCLAIR, N. J.

A GREAT deal has been said and written of late in regard to the hygiene of school life. It seems to be generally conceded that the health of many scholars is injured by their school work, and there is a growing tendency to blame the teachers for driving the pupils beyond the limit of their strength. As the writer has from time to time looked over the educational field for about thirty years, and was himself at one time a teacher, he naturally takes considerable interest in this very important question.

While it seems that teachers are frequently to blame for urging children to study beyond their strength, this mistake would appear to be, in a measure at least, in consequence of ignorance of the limits beyond which the delicate organization of the growing child should not be urged. Teachers themselves appear to need more thorough education in hygiene and physiology, as well as in physical training.

On the other hand, there is no question that they are often far less to blame for pushing their scholars too fast than the parents, and, in some cases, the children themselves. The giving of prizes and marking the scholars competitively so that the spirit of rivalry and emulation is excited is distinctly bad; and as this has apparently always been a prominent feature of our public school education its evil influences are everywhere apparent; although fortunately the pernicious practice of inciting scholars to do well for the sake of surpassing their colleagues is now being superseded; publishing graded marks, giving prizes, etc., having been so largely abolished.

Now, however, the parents and the children are constantly menaced with the fear that the latter will not be promoted at the end of the year, and if any one fails of promotion he fears that the finger of scorn will be pointed at him, and his parents act as though they feared a loss of social prestige if their offspring should be set back a year. It seems probable, however, that the baleful influence of parental vanity can be measureably overcome by appeals to reason and moderation. People must be made to understand that it is no disgrace if their children are not so strong, nor so receptive as their neighbor's child. It will be an immense gain when the parents shall be made to understand that the mental vigor depends largely upon the bodily health.

By taking thought we cannot add a cubit to our children's intellectual stature, any more than we can to their bodily stature. The child's mind must not be stretched to fit the system, but his intellectual capacity must be carefully weighed and measured, and he must take that place in the graded school which he is capable of filling.

Amongst others, Edward Everett Hale has recently inveighed against "the mechanism of the public schools." But it must be borne in mind that the public schools are fulfilling a great function in trying out and classifying their scholars. Hard as the system may seem to be in certain cases, it is, on the whole, a good and beneficent system; although it may seem needlessly harsh to the parents of weak and dull scholars, still it must be admitted to be a great and lasting advantage to ascertain the mental and bodily limitations of every scholar as early as possible, and upon this foundation to proceed to build up his education in the most judicious manner. Instead of condemning and antagonizing the teachers, parents should co-operate with them, by carefully watching their children, and by conferring with the teachers they can ascertain whether the former are working up to the limit of their strength or beyond it, or whether, on the other hand, they are slighting their work. This I am satisfied, only comparatively few parents do systematically, and much of the dissatisfaction which is expressed against the schools is really the fault of the parents; and, furthermore, the bitterest and most vehement complaints come from parents who really understand least about the matter.

My own experience, and I presume that of others also, leads to the conclusion that the school work bears much harder upon girls than upon boys. While there are, so far as I know, no available statistics relating to the point, I dare say that no one will dispute this assertion. Admitting for the sake of argument, that it is desirable and proper for girls to go through our public grammar and high schools, and to take the same courses as the boys, how are we to prevent the injury to their health which many of them sustain while doing this? While the question is a difficult one to answer, its great importance will presumably lend interest to certain suggestions upon the subject.

In the first place, girls have a decided handicap as compared to boys by reason of their greatly inferior physical equipment. Professor Pierce of Philadelphia once said, in my hearing, that the strain of the high-school examinations in his town ordinarily showed itself in the resulting injury to the teeth of the school girls; whereas the boys, interested in baseball and out-of-door sports, showed no dental decay at examination time. This to my mind is a striking proof of the fact that the girls are working more beyond their strength than the boys, because in this regard the two sexes can be fairly compared, whereas the saying that 75 per cent. of school girls suffer from menstrual irregularities, while sufficiently disheartening, does not allow of comparison with boys. Scoliosis and chlorosis are much more frequent in girls than in boys, and in many instances no doubt are the evil results of over work and bad hygiene during school life. An old surgeon of wide experience once told me that he had found that fractures did not unite as favorably in girls as in boys. A recent writer has said that of the children who enter the hospitals for physical defects in, I believe, Boston, hardly 5 per cent. are boys. All these statements tend to show that girls are much weaker physically than boys, and that their *more frequent break-down in school is to be expected;* provided the same amount of work is required of both.

Is this physical inferiority inevitable? Or can we so prepare and train our female children that they shall be as hardy as their brothers?

This question opens a wide field for discussion into which we cannot enter now, except to point out the obvious fact that if girls are to go through the same courses of study as boys, it is only fair and right that they should have as good a preparation. Instead of being turned out to play in the sun bare-footed and bare-legged until they are eight or ten years old, women begin their earthly pilgrimages with the same handicap that they bear to the end, viz., a never-ceasing, unremitting, all pervading care for their clothes. As soon as they can understand the meaning of language they are warned not to soil their clothes. They are made to look pretty, and are set up to be looked at from infancy upward. Their natural physical indolence and timidity are augmented in every way by precept and training. Fortunately, many of the older girls play golf and do other things to develop their bodies, but the physical well-being of little girls is criminally neglected. It is in these early years that they must acquire that muscular and nervous tone which shall carry them safely through the storms of puberty and the fierce grind of the public school. Can they acquire it at all? The question is an exceedingly interesting one. Until little girls, as a class, get the same out-of-door life that little boys do, we cannot say whether they will develop the same nervous resiliency or not, and without such experimental knowledge, generalizations on this head must be more or less conjectural.

From observation on the lower animals there seems to be little difference in endurance between the sexes. The squaws amongst our native indians have nearly as much endurance as the braves, and in many cases apparently more physical strength; so far as known, these women escape neurasthenia and the other troubles peculiar to their sex. It is only so-called civilized women, amongst which the Chinese should be included, whose dress, habits and training so markedly hamper them in doing their part in the world, whether as students, workers, or mothers. We must begin the physical education of our women earlier and make it more thorough, and we must dress them differently all their lives if they are to have anything like an equal chance with men as workers, or if they are to come anywhere near fulfilling their possible destinies.

It is just as true now as when Lysander said it "that the fate of a nation's prosperity depends upon the bodies of its women," and it is just as true that perfect bodies can only be produced out of good material by the utmost care; and lastly, let it never be lost sight of that, with a few exceptions, which are more apparent than real, a sound mind cannot exist outside of a sound body.

PROSTATIC GONOCOCCAL AUTO-REINFECTIONS OF THE URETHRA.*

By TERRY M. TOWNSEND, M.D.,
NEW YORK.

In a recent publication Dr. Valentine[1] has directed attention to urethral gonorrhœal auto-reinfections from gonococci remaining residual in the urethral stroma and adnexa, and pointed out the difficulties attendant upon the cure of these obstinate conditions. It is with the hope of supplementing this subject that the following observations of gonorrhœal auto-reinfections of the urethra are offered.

Of the complications of gonorrhœa, prostatitis is the most frequent. Most writers agree that posterior gonorrhœal urethritis is almost invariably followed by gonorrhœal prostatitis, Von Frisch[2] forcibly remarks that "almost no case of acute posterior gonorrhœal urethritis occurs without infections of the glands." A study of the methods of prostatic infection causes surprise that any gonorrhœic escapes prostatic involvment.

While direct extension of the gonorrhœal process to the prostatic gland ducts is the most frequent route of infection, this cannot account for many cases in which the posterior urethra seemingly retains its integrity.

Grosglick[3] suggests that posterior urethritis may occur and disappear without observed symptoms during the interval between the patient's visits to his physician. Wossidlo[4] believes that the posterior urethra in some cases possesses an immunity which allows gonococci to traverse its length and infect the gland without producing urethral symptoms Another method of prostatic invasion is suggested by Lewis[5]. He believes, with Rona of Buda-Pesth, in the possibility of gonococci entering the posterior urethra and prostate through lymphatic anastomoses between the anterior and the deep urethræ. Still another method is suggested by Lydston[6], who likens the posterior urethra during ejaculation to the rubber bulb of a syringe He assumes that the first few contractions of the perineal muscles force the seminal fluid into the anterior urethra and the succeeding contractions and relaxations aspirate the semen, mixed with anterior urethral secretions, into the posterior urethra.

Through whichever method or whatever route the infection occurs, neglected, misdirected, or omitted treatment will result in a chronic gonorrhœal prostatitis, whose recrudescences constitute a never ending danger and annoyance.

For convenience of consideration, these recrudescences may be classified into (1) Those which occur before convalescence is established; and (2) Those which occur sometime after the cessation of all symptoms. That the recrudescences occur in this manner may be explained by the pathology of gonorrhœal prostatitis.

In the lightest and most frequent type of infection ("der acute gonorrhoische Katarrh der Glandulæ prostaticæ"—Finger[7]), only the ducts of the prostatic follicles are affected. "The disease phenomena of this lightest form of prostatitis can hardly be observed alone, as they are so fully covered by the pregnant symptom-complex of acute posterior urethritis." (von Frisch[2]). The best evidence of this condition is the presence of curled filaments in the urine, first described by Fürbringer,[8] consisting of mucus, pus corpuscles, prostatic epithelia, and usually rich in gonococci.

Given this form of prostatic infection, a urethral discharge or excess of moisture free from gonococci, clear urine containing perhaps but few filaments; any mechanical dislodgement of the contents of the inflamed ducts will most likely result in an exacerbation of the urethral discharge and rapid proliferation of gonococci.

It is when the gonorrhœal process proceeds to the prostatic follicles and becomes subacute or chronic that the pathological changes in the gland occur, which makes possible the auto-reinfections seen after intervals of apparent health. These changes consist of small round-cell infiltration into the peri-glandular tissues, which later take on a cicatricial character, resulting in stricture or obliteration of the ducts. From this connective tissue change, the follicle and remaining part of the duct acquire a racemose appearance, are filled with desquamated epithelia and pus corpuscles, and in many cases the original infectious bacteria.

The causative factors in the dislodgement of this plug of mucus epithelia and pus are usually coitus, nocturnal pollutions, the masseur's finger, and sexual excitation without gratification. However, these will not explain the recrudescences occurring years after apparent cure. Valentine[9] reports such a case after twenty-five years of healthy marital life. In this case manifestations of incipient, senile hypertrophy of the gland was the motive for consultation. The writer has observed one case of this type, in which the only traceable cause was a period of prolonged physical and mental exertion

The symptomology contains a few interesting features which differ from those of acute anterior gonorrhœa. Ardor urinæ is usually absent and the patient's first indication of an abnormality is a sensation of dampness around the genitalia or stains on his shirt. Unless the condition be recognized at once, and the prostate vigorously treated, acute posterior urethritis and an acute recrudescence of the prostatitis occurs. In this event the prostatic symptoms predominate.

---

*Presented before the American Urological Association at Saratoga, June 13, 1902.

If the gonorrhœa be of recent acquisition, in the majority of cases studied, the prostatitis has shown decided tendency to parenchymatous inflammation and to abscess-formation. Cases of the second type, where gonorrhœal infection has been of years before, the prostatitis nearly invariably remained follicular, because of the endogenous cicatricial connective tissue in the parenchyma.

The symptoms of prostatitis have been so well detailed by master pens that their recapitulation is unnecessary. The urethral symptoms vary directly with the intensity of the exacerbations of the prostatitis; the discharge and turbidity of the urine diminishing with increased prostatic engorgement and increasing as the inflammation subsides.

After the diagnosis of gonorrhœal urethritis is made, the differentiation between an acute infection and a prostatic recrudescence is more perplexing and, after the lapse of a few days, even impossible. This differentiation assumes importance, because upon it depends the direction of intelligent treatment, and not infrequently the re-establishment of conjugal felicity. The following symptoms of acute infections are opposed to those of prostatic recrudescences:

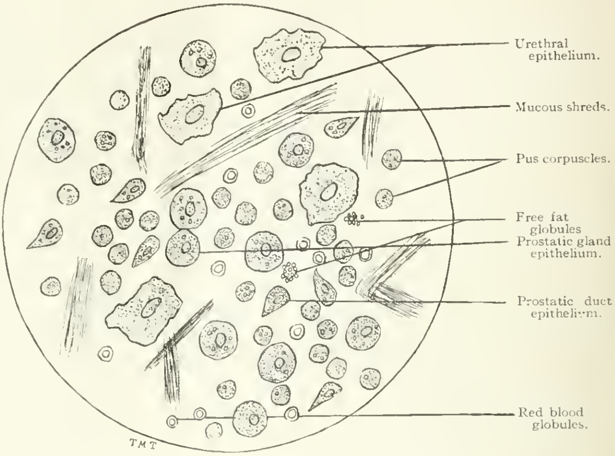
IN PROSTATIC AUTO-REINFECTION.	IN ACUTE INFECTION.
History of a precedent gonorrhœa, with posterior invasion.	May or may not have had a previous gonorrhœa.
A short incubation period: twenty-four to forty-eight hours.	The usual period of three to ten days incubation.
The stain is much larger in proportion to the discharge.	The stain on the cotton covering the meatus is commensurate with the urethral discharge.
Meatus is somewhat puffed and its lips pouting outward.	Meatus is usually reddened and eroded.
First portion of urine usually clear and containing the curled filaments of Furbringer.	First portion of urine almost invariably turbid.
Discharge unaffected by anterior urethral treatment	Discharge is reduced by anterior urethral treatment.
Abrupt onset of acute posterior urethritis.	Gradual appearance of acute posterior urethritis.
Appreciable pathological changes, per rectum.	Gland, normal, per rectum.

Since the symptoms are not always constant, and may be masked by disease phenomena not here considered, the microscopic features of the urinary sediment are worthy of closer study.

Accepting Heitzman's[10] differentiation of epithelia in urine sediment, the features found in the incipiency of prostatic auto-reinfections of the urethra are here tabulated, with a consideration of their significance:

1. Pus corpuscles depending in number on the purulence and intensity of the disease.

2. Red blood globules—depending upon the area and intensity of urethral involvement.



Features Found in the Urine Sediment in Chronic Gonorrhœal Prostatitis, with Acute Auto-reinfection of the Urethra. × 500.

3. Epithelia from the prostate gland and its ducts. These preponderate in number over other epithelia found in the urine and are filled with globules of fat, indicating that the chief lesion is prostatitis and that the condition is chronic. Few of the epithelia from the gland contain endogenous new formations, showing the effect of the pressure by the peri-follicular exudate.

4. Epithelia from the urethra, varying in number with the area and degree of intensity of the urethritis.

5. Epithelia from the urethra, near the vesical neck.

6. Epithelia from the middle layer of the bladder. Heitzman (op.cit.) finds these two latter varieties of epithelia in the majority of cases.

7. Mucus threads abundant, as is the rule in all genito-urinary inflammations.

8. Fat globules—free, and in the epithelia and pus corpuscles. They indicate a degenerative metamorphosis and signify chronicity.

Taking these features for a premise, the following reasoning is logical. Prostatic epithelia studded with fat globules and some containing endogenous new formations, indicate a chronic prostatitis, hence this is the previous lesion. Urethral epithelia, from both strata and red blood globules denote acute urethritis, necessarily acute because of the absence of the fat globules in the epithelia and the presence of red blood globules. Therefore, the diagnosis of chronic prostatitis with acute urethritis is inevitable. The infective nature of the disease can be demonstrated by staining a filament or the urine sediment for gonococci. Oftentimes stained specimens show prostatic epithelia containing diplococci with the morphology and staining properties of gonococci. This fact is conclusive proof of the correctness of the diagnosis. In many cases other features are found in the urine sediment from concomitant or preexisting lesions, but these are afield from present consideration.

While the prostatic infection remains a simple catarrh of the gland ducts, cæteris paribus, the prognosis for rapid and complete recovery is good. Unfortunately, the extension is seldom recognized in time to prevent its further progress. Frank[11] suspects and searches for this complication within the first few days of the disease and attains success by vigorous treatment.

The prognosis in prostatic recrudescences occurring some time after the cessation of subjective symptoms must be guarded. Ordinarily, the urthritis yields kindly to treatment, but the prostatic foci of gonococci are not easily eliminated. Those prostates which present a large area of diseased tissue, many nodules of hardening and spots of softening, and of long duration, are most difficult to cure. Van der Poel[12] thinks that catarrhal inflammation previous to the gonorrhœal infection is the cause of these softened spots, and predisposes to a gonorrhœal follicular prostatitis. This will, in part, account for the obstinate persistence of points of hardening and softening even after prolonged treatment. It is well to reserve opinion as to the probable duration of such conditions, and even after the disappearance of disease phenomena to warn the patient of possible future auto-reinfections.

Rational treatment demands simultaneous attention to the prostate and the urethra. This may be accomplished by thorough massage of the gland followed by irrigation of both urethræ. Many of the simple infections of the ducts do not require massage. Von Frisch[2] says "the treatment of acute catarrhal prostatitis coincides with the treatment of acute posterior urethritis." However, if there is the slightest suspicion of follicular invasion and especially if prostatic epithelia abound in the discharge or urine sediment, massage should be instituted. Under any circumstances, this procedure, properly conducted, cannot produce untoward results.

In many cases of chronic prostatitis, effective emptying of the follicles is difficult, in some instances because of the hard fibrous condition of the gland, and in others because of its high location in the pelvis. Mechanical devices to aid the massaging finger have been proposed by several authors, but have not accomplished the results that justify their use.

The frequency with which prostatic massage may be done is quite variable. Ordinarily, afebrile cases of mixed follicular and parenchymatous types bear daily massage well. After six or eight days the interval between massages may be lengthened one day until five or seven days are reached. Old follicular prostatites do not seem to tolerate treatment oftener than every third day, increasing the interval *pari passu* with the improvement.

In the prostatic treatment the following ends must be attained: (1) Evacuation of the infecting focus or foci; (2) Effective emptying of other diseased follicles; (3) *Restitutio ad integrum* of newly-infected areas.

The management of the urethritis does not materially differ from that of acute gonorrhœa, except that intravesical irrigation may be done from the beginning of treatment.

When a stenotic meatus, stricture, or urethral infiltrations exist, instrumental treatment may be instituted in the interim between massages, thereby gaining time in the cure.

The selection of the irrigating fluid depends upon the microscopic findings, silver preparations being preferable when gonococci persists. When gonococci disappear, other bacteria remaining, *e. g.* colon bacilli, strepto- or staphylococci, solutions of corrosive sublimate are indicated; where no bacteria are demonstrable, astringents.

Summary.—1. Early and vigorous efforts should be made to prevent gonorrhœal prostatitis.

2. Once established, all care should be taken to prevent it from becoming follicular and chronic.

3. Auto-reinfections of the urethra from chronic prostatitis can be differentiated from acute infections.

4. An opinion on the probabilities of future recrudescences should be very guarded.

5. Each prostatic massage should be immediately followed by thorough irrigation of both portions of the urethra, to prevent recurrent acute urethritis.

6. Omission of this irrigation is sometimes permissible for diagnotic purposes.

Major Ross and His Reward.—A "coronation honor" about which little or nothing has been said was the award of a companionship of the Bath to Major Roland Ross. Assuming that this was in recognition of Major Ross's discovery that a parasite of the anopheles mosquito is the cause of malaria in man, the reward is a meagre one, especially when compared with those which went to soldiers and politicians whose services to humanity are infinitesimal beside those of this able and industrious surgeon. To find the relation between mosquitos and malaria was to confer benefits absolutely immeasurable—it amounted to a doubling of the earth's safely habitable area, to a marked decrease in the general death rate, and to an enormous diminution for succeeding ages of the aggregate of human suffering. Of course Major Ross has had many fellow-workers, including scientists in many lands, but he opened the field of investigation, and he has labored at least as successfully as any of the others in the practical campaign against the insect once regarded merely as a sorry joke, but now recognized as the bearer of certainly two, and probably several more, terrible diseases. To equip a man like this with a title reminiscent of servile tasks once deemed honorable when performed for royalty is fortunately amusing as well as absurd. Otherwise it would be outrageous. The matter however, is not one to be considered seriously. Major Ross's real reward is the frequent coming nowadays of news like that from Dar-es-Salaam, German East Africa, where anti-malarial measures suggested by him and begun in 1901 have already produced marked effects, and promise within five years, as the British Consul there reports, "to change the town from a plague spot to a sanitarium."—*New York Times.*

THE EFFECT OF FERRIC PERCHLORIDE IN LARGE DOSES IN ERYSIPELAS AND SIMILAR INFLAMMATORY DISEASES.

By JENNIE G. DRENNAN, M.D.,
ST. THOMAS, ONT., CAN.

ERYSIPELAS is an infectious disease due to the invasion of the skin by streptococci, which cause an inflammation of this tissue with constitutional symptoms. In its uncomplicated form there is to be seen little else than inflammatory œdema. The cocci are found chiefly in the zone of spreading inflammation and in the lymph spaces. The streptococci, having gained access to a certain part of the skin, multiply and produce excretions deleterious to the tissues with which they come in contact, the capillaries which are contained in this area become disabled. "Inflammation is the succession of changes which take place in a living tissue, as the result of some kind of injury, provided that this injury is not sufficient to immediately destroy its vitality"—and are unable to carry off their poisonous substances, which go on accumulating until they overpower their producers and cause their death—every animal has the power to commit suicide, to drown itself in its own excretions. The succession of changes which occurs in an inflamed area results in stasis of the circulation, the exudation of liquor plasma and the escape of white blood corpuscles. On the escape of this fluid and corpuscles into an inflammatory area or into a foreign surface there is the formation of fibrin, the fibrin ferment being liberated from the corpuscles and acting on the only fibrin factors in the fluid. This fibrin enmeshes the bacteria and renders their escape into surrounding tissues difficult, and also renders them an easier prey to their own secretions, which are now more unable than ever to be carried off. This forming of a clot, or as it is called on the surface of a mucous membrane, a false membrane, is Nature's method of effecting a cure; a conservative process by which poisons are localized.

Ferric chloride is not given in these diseases for its hæmatinic action, for if so, very much smaller doses would be all that would be required, for the amount of iron taken up by the red blood corpuscles is, indeed, small (.42); but it is rather for another effect. The circulation being obstructed in the diseased area, the ferric chloride will not enter this area, but will circulate in the vessels just outside of it, and here it exudes from the capillaries into the tissues in which they lie—Iron's astringent effect is not exerted as that of silver or lead by actively contracting the small vessels, but by diminishing their size by pressure from without. This action of iron increases a clotted or unsuitable area in which any bacteria which have so far escaped being entangled are prevented from advancing into new fields. The first was nature's barrier, this is a chemical one. It takes large quantities of iron to produce this coagulating effect; hence large doses. In smaller tonic doses this would not be accomplished.

We have thus a coagulated area which is a coagulated area, one produced by disease, the other by medicine. From the vessels of the latter, when they are released from the compression from without, an exudation of liquor sanguinis and an escape of white corpuscles takes place, and these wander into the coagulated area, and reorganization takes place much as non-vascular tissue is regenerated from the surrounding vascular tissue.

Bacteria kill themselves by their own excretions. Immunity to disease is the result of these excretions still circulating in the blood. Bacteria coming in contact with them perish.

Why do bacteria not cause disease in a healthy person, and why do they cause it in an unhealthy person or in one who has some weak spot? Bacteria entering the tissues of a healthy body are at once attacked by their normal leucocytes which have normally escaped from the blood vessels of the part attacked; these overpower the invaders; but in a tissue whose vitality is in the least lowered these bacteria come in contact with an increased amount of liquid plasma and an increased number of escaped white corpuscles; but in this instance Nature's first attempts are not to overpower the invaders, but, first of all, to form a clot or coagulated area in the vicinity of the capillaries, and the greater number of the white-blood cells yield up their fibrin ferment, which acts on the fibrin factors of the liquor sanguinis and fibrin is formed, the bacteria being then enmeshed in this and killed by their own excretions. In the healthy body there is no need of this, and the leucocytes at once attack the bacteria. How do they accomplish this? Is it possible that the fibrin ferment contained within them has an injurious effect on the germs? It is in the low grades of inflammation that bacteria flourish best, for here Nature's preventive to their advance is slower in being formed (a fibrinous clot).

VAGINAL OPERATIONS FOR RETROVERSIONS AND RETROFLEXIONS OF THE UTERUS, WITH A CRITICAL REVIEW OF FIFTY-SEVEN CASES OF VAGINAL SUTURING OF THE ROUND LIGAMENTS (THE AUTHOR'S OPERATION).*

By HIRAM N. VINEBERG, M.D.,
NEW YORK.
ADJUNCT GYNECOLOGIST TO MT. SINAI HOSPITAL AND ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

THE old and much-abused vaginal fixation of the uterus (the Mackenrodt operation), in my opinion, still forms the ideal operation for a certain class of cases of retroversions and retroflexions of the uterus. These cases are: (1) Cases of retroversion, giving rise to symptoms, in women past the child-bearing period, or, let us say, in women past the fortieth year. It must be understood that the operation is indicated only when for some reason or another a pessary cannot be worn or cannot keep the uterus in good position. It is not my province in this brief paper to enter into the details which proscribe the use of a pessary. It will suffice for me to state here that I make use of one in these conditions when it is capable of accomplishing the desired result. (2) Cases of retroversion in women approaching the menopause, in which the retroversion is associated with a marked degree of prolapse and a marked rectocele and cystocele. Pessaries in these cases are of little or no avail. The vaginal fixation forms only one of a series of operations that are indicated, and which are performed at the one sitting. As a rule the additional operations called for are (1) Amputation of the cervix; (2) Anterior colporrhaphy; (3) Posterior colporrhaphy; (4) Perineorrhaphy. I deem it necessary, in order to obtain a permanent anatomical result, in performing vaginal fixation in these cases to open the peritoneal cavity and to suture the anterior surface of the fundus directly to the vaginal wall. Having opened the peritoneal cavity, it is wise to directly inspect the adnexa, and if found diseased to treat them on conservative surgical principles. I was the first in this country to perform vaginal fixation (my first operation being done in 1893), as I was also among the first in this country and elsewhere to do plastic work upon the adnexa through a vaginal incision.*

---

*Read at Obstetric Section of Academy of Medicine, May 22, 1902.

When we have to deal with women of a less advanced age, in whom the child-bearing period has not yet been extinguished, vaginal fixation has some serious drawbacks, as has been pointed out by several writers, including myself.†

For women of this age I resort to vaginal suturing of the round ligaments, the operation which I devised in the early part of 1896.‡

It ought to be a wise and profitable thing to review one's results in a certain line of work from time to time. The review attains considerable scientific value if it be based strictly on accurately-observed facts, and if it be not tinctured over much with the bias one naturally feels, so to speak, for his own offspring. It will be my aim to live up to these requirements in the analysis of my cases which I shall present to you to-night.

In May, 1900, in a paper read before the American Gynecological Society,§ I presented, in tabulated form, the results of my operation in fifty cases, embracing the cases operated upon from February 4, 1896, to November 10, 1899. I could then say of these fifty cases that forty-seven were attended with anatomical success, *i. e.* the uterus remained in a good forward position for a period varying from four to five months. At that time I was able to report four pregnancies going to full term and having easy and normal labors. There were then, so far as I knew, no cases of miscarriage, nor of dystocia. My anticipations, therefore, as to freedom from disturbances during pregnancy and parturition from the operation were thus far fully realized.

Subsequent to the publication of that paper one of the cases (case 40) miscarried at the twelfth week, while she was abroad and traveling a great deal. I saw her some months afterward, and learned that she continued on her travels a few days after the miscarriage. I found the uterus in complete retroversion. It is reasonable to assume that had she been more discreet during her pregnancy the miscarriage might not have occurred. The recurrence of the retroversion is certainly no cause of surprise when one considers that two days later she was on her feet again and travelling from city to city. Still, to be strictly accurate and to leave no room for fault-finding by the most carping critic, I place the case in the list of failures and of miscarriage following the operation.

Another case (case 48) that was put down in the report as a therapeutic failure, later became entirely freed from pelvic symptoms, and had a miscarriage at the eighth week in October, 1900. She then became pregnant again in December of that year, went through a normal pregnancy, and was delivered of a male child at full term in September, 1901. I examined her some months afterward and found the uterus in excellent position, and the patient entirely free of symptoms. I have had occasion to examine several of the other patients in the reported series, and the foregoing case constituted the sole relapse. Some of the cases, therefore, have now been under observation for a period of over six years.

Since November 10, 1899, the end of the period embraced by the tabulated report, I have operated upon seven other cases, all of whom made a smooth recovery after the operation. There has consequently been no mortality in the fifty-seven consecutive cases, and only in three of the first series had the convalescence been disturbed by any complication. These results with an operation, covering a period of six years, and done under variable conditions, some of which were very unfavorable, as when operating in tenement-houses, must refute the objection raised by some as to the difficulties of rendering the field of operation aseptic when operating through the vaginal route. It must be borne in mind that in every case the peritoneal cavity was entered, the adnexa brought into view for direct inspection, and in 70 per cent. of the cases more or less plastic surgery was done upon the adnexa.

Of the second series of seven cases none has been operated upon later than September, 1901. They have all been frequently examined since then, and only one has shown a relapse. There were three relapses in the first series of fifty cases, but two of these occurred in cases of congenital retroversion, in which no operation, so far as my experience goes, is attended with success. These two cases may, therefore, be properly excluded, and we thus have two relapses in fifty-five cases or a percentage of anatomical failures of 3.6 per cent., or an anatomical success of 96.4 per cent.

On looking up the notes of the case of relapse of the second series I find that only one suture was employed on each side, while in the majority of the cases I have applied two sutures on each side. It would seem wise, therefore, not to trust to a single suture, but in every case to make use of two sutures for each round ligament.

The small number of cases operated upon during the past two and a half years may require an explanation. This may be found in the following circumstances: First, my material has been drawn during this period from a better-to-do class, from a class who can afford to rest, and in whom the use of mechanical supports or other palliative treatment can be carried out with a good degree of success.

Secondly, having operated upon a fair number of cases, I was desirous to wait, and to note the behavior of pregnancy and labor in those who might happen to conceive before subjecting any more to the operation. I think I may safely state now, after an observation of six years, that there need be no fear of dystocia following this method; but I will speak of this more fully later on.

It would appear that every one aspiring to be a gynecologist nowadays deems it necessary to devise a new method for anchoring the uterus in a forward position. This is unfortunate, for no sooner is a method advocated than it is superseded by some modification, either by the originator himself or by some one else. The result is that the number of operations advocated for backward displacements is legion, and no one operation or method offers any data for a respectable period of time by which to judge of its merits or demerits. It is with these operations as it was in days gone by with pessaries, when every one thought he had to invent one, and I venture to predict that the fate of these numerous fantastic operations will be the same as that which befell the odd and curiously-shaped pessaries.

It is interesting to note the roundabout methods, in order to be original, some operators will adopt to carry out a simple principle. To select a couple of instances from a great number: One operator dilates both internal abdominal rings, so as to be able to inspect through them the adnexa on either side, and then sutures the round ligaments to the pillars of each ring. How much simpler it is to make a small median incision through which both adnexa may be inspected and treated surgically if necessary, and then suture the round ligaments to the abdominal wall. This constitutes the Olhausen's method. It has stood the test of time, and has never as yet been followed by dystocia. The same applies to the vaginal route. Why try to perform all kinds of fantastic tricks with the round ligaments; as, for instance, making them pass from one side to the other through a canal made in the uterine tissue, when the simplest and most reasonable thing to do is to suture them to the vaginal wall?

---

*Vaginal Cœliotomy, etc.—THE MEDICAL RECORD, March 2, 1895.

†I must, however, repeat here what I said on a former occasion, that, as far as my own experiences go, the only serious result I have known to take place in my cases was the occurrence of abortion in some of the cases. My cases of vaginal fixation in women during the child-bearing period number over fifty, several have gone through a normal pregnancy and a normal labor. In none, as far as my knowledge goes, was dystocia observed. It was only the other day that I again examined my first case of vaginal fixation, done in 1893. The patient went through a normal gestation and puerperium a few years later, and at this day the uterus is in excellent forward position.

‡*Medical News*, March 14, 1896.

§*The American Journal of Obstetrics*, August, 1900.

The behavior of pregnancy and labor in cases in which the operation was performed will constitute the crucial test as to the value of the operation. I can now report eight pregnancies in six patients, going to full term and terminating in easy and normal labors. There have been two miscarriages, one of the patients subsequently carrying to full term and having a normal labor. The occurrence of the miscarriages ought not to count against the operation, for as we have seen in the one case, it, no doubt, was brought on by imprudence; and in the other it could not well be due to the operation, inasmuch as the patient went to full term in a subsequent pregnancy, the uterus remaining in the position it was placed by the operator. As I have stated on a former occasion, the occurrence of a miscarriage in a uterus that has long been in retroversion cannot always be charged to the technique that may have been followed to anchor the uterus in a forward position. And for this reason, a uterus that has long lain in an abnormal position becomes the seat of a chronic metritis, which does not readily disappear, even after the uterus has been placed in proper position.

Now, we know chronic metritis is frequently the cause of a miscarriage even when the uterus has always been in a normal position, and why cannot it also be the cause in a case in which the uterus has been placed in a normal position artificially?

Be this as it may, however, the chief desideratum in an operation to anchor or suspend the uterus forward is whether it is to be followed by difficulties at labor. It seems to me that, on the strength of the data I have thus far been able to collect, I can safely venture the opinion that there is little likelihood of dystocia following the operation that I have devised. Although it must be granted that the number of cases as yet is rather small to justify a positive opinion, still the experiences tally so completely with the theoretical considerations that I I feel justified in recommending the operation without any fear on that score. But I must emphasize a point referred to in my former paper, that, in order to reduce the risks of dystocia to practically *nil*, the greatest care must be taken not to wound the anterior wall of the uterus in bringing it into vaginal incision. For were one to be careless in this step of the operation and cause a large raw surface of the uterine wall, a condition would be created which might be followed by a firm union of the fundus with the vaginal wall. Then we would have a similar state of things to that which is intentionally brought about in the old vaginal fixation, and which proved to be so frequently a cause of dystocia. But the uterus can readily be delivered through the vaginal incision by the aid of a couple of traction sutures, and there is no need of creating a raw surface on the uterine wall. To make assurance doubly sure I always suture the incision made in the peritoneum after having first passed the fixation sutures about the round ligaments.

Larger and more extensive experience with the operation has convinced me of its utility in a certain class of cases, in those in which (*a*) the uterus is movable and a pessary cannot be worn; (*b*) the uterus is more or less fixed by posterior adhesions (*c*) in the same class of cases with moderate diseases of the adnexa.

From the nature of the different lesions in different cases it is not reasonable to assume that the same technique is suitable in all cases. Each case must be carefully studied and the method selected which seems to be the most suitable for that case.

In my own experience, roughly speaking, about 75 per cent. of the cases that I meet with are adapted to the operation of suturing the round ligaments to the vaginal wall.

751 MADISON AVENUE.

Milk Sickness.—W. J. Collins defines this as an acute infectious disease, occurring both in man and in the lower animals, characterized by "trembles," and disordered functions of the alimentary canal. The gastrointestinal tract is the gateway of infection. The author describes the symptoms in detail. In favorable cases the course of the disease is long, and there is a great tendency to relapse. The prognosis is not very favorable. About 40 per cent. of the author's cases died. Symptoms are to be treated as they arise. Strong purgatives are contraindicated, but constipation should be combated by enemata and calomel. Bismuth and hydrastis should be given to control vomiting. Strychnine and digitalis are indicated. Rest is the most important point in the treatment. Prophylaxis consists in the prevention of disease in cattle by keeping them away from all places where they are liable to contract the disease. In infected districts all milk, and milk products and beef, unless well cooked, should be avoided, for the milk of a cow which may appear healthy may be very poisonous. Writers devote too little space to this disease, and are apt to state that it exists only in parts of North Carolina. Although the disease is waning, it is not entirely eradicated in a number of States, and it is of paramount importance that practitioners in these States should know how to recognize and treat the disease.—*The Medical Standard.*

The Mattison Method in Morphinism.—W. P. Ivey extols this method, which consists in rapidly filling up the patient with bromide of sodium, and at the same time rapidly reducing the amount of the narcotic. The patient *must* be put to bed, as absolutely as if he were in the third week of typhoid fever, and he must have a reliable nurse, whose sole duty it is to stay with him all the time. The physician now begins with an initial dose of ten grains of sodium bromide twice daily, increasing the dose ten grains each day for seven days. The author inclines to think that in general practice thirty grains would be better for an initial dose. At 4 P.M. and 4 A.M. a dose of the bromide is given, and at 10 P.M. and 10 A.M. a dose of the accustomed narcotic. For the first few days the opiate is given in gradually diminishing doses and afterward when the patient is becoming bromidized the dose is diminished more rapidly; the last dose being given not later than the tenth day. The Mattison method possesses no advantage over any other in making the cure permanent. As in any other treatment, the patient must not be dismissed too early, but must be considered a patient for several weeks, and be given tonics and restoratives, and kept away from temptation.—*The Carolina Medical Journal.*

THE ARMY SURGEON IN CROMWELL'S TIME.

It is fair to assume that, since the time when organized bodies of fighting men first came into existence, along with those whose duty it was to maim and kill the enemy, went others whose task it was to relieve the sufferings and, if possible, save the lives of those whom the enemy's weapons had injured. But probably at all times, as now, these men of healing were regarded with scant favor, and were simply tolerated by their fighting comrades because of their occasional usefulness in patching up a dissected warrior. History has little to say of them, and it is only by a word let drop now and then that we know they existed as a recognized body.

The author of a recently-published account of the army serving under Crowmell*, Mr. C. H. Firth, has devoted an entire chapter to the sick and wounded among the soldiers of the Protector, and in it we find many curious and interesting details.

Many people think that the immunity and quasi-neutrality of ambulances and their staff date only from the Geneva Convention, yet 250 years ago, in the Civil wars, surgeons were treated as non-combatants by both sides. Mr. Firth says: "When in the field they probably wore a distinguishing badge according to the practice of earlier times." "Surgeons," says an Elizabethan writer, "must wear their baldric, whereby they may be known in time of slaughter; it is their charter in the field." Distinguishing badges were also needed by the combatants in order that men might tell friends from enemies, for until the modern scarlet was adopted by the parliament, Royalists, and Roundheads were indistinguishable by their dress. Before an assault or a pitched battle, orders were often issued as to the badge to be carried. At Edgehill the Parliament's troops wore orange scarves.

When their own wounded were in the hands of the enemy it was not uncommon for surgeons to be allowed to visit and to treat them. For the honor of our professional forebears, it is to be hoped that the army medical corps of his day was not an accessory to the "slim" behavior of Colonel James Hippisley in Ireland. This enterprising officer disguised himself as a surgeon, and thus got access to an Irish castle which his troops were besieging, and, after spying out its weak points, headed the storming party which took it. Evidently such abuse of privileges was rare, or they would soon have ceased to be granted. Barnaby Rich, in his "Pathway to Military Practice," published in 1587, half a century before the outbreak of the Civil War in England, had written: "A good and skilful chirurgeon is a necessary man to be had in a companie, such an one as should worke according to arte, not practisinge newe experiments upon a poore souldier by meanes whereof many have been utterly mayned by a chyrurgeon's practise that otherwise might have doon very well." This has a familiar ring. Its echoes are heard in ill-informed complaints of the "incompetent army doctors" of the twentieth century. But the army surgeons could neither cure nor please everybody. Turner, in 1671, complained of them, and demonstrated the obvious wisdom of employing "none but good and experienced artists." There seems to have been at least one surgeon to every regiment, who, "besides his monthly pay, should have his Surgeon's Chest, furnisht with all manner of Necessaries for curing Wounds of all kinds; and this chest is to be furnisht at the Prince's charge [this was written in 1671] and all wounds received in the Prince or State's service, he is obliged to cure (if he can) without demanding anything from the Patients, but all others got accidentally, or by quarrelling and Duels, he is not obliged to cure but for payment, in which the officers are bound to assist him."

When in 1650 Cromwell set out for Scotland, each regimental surgeon was ordered £15 to pay for a chest and £10 for a horse to carry it. A year later we find that the pay of the regimental surgeon was six shillings a day. In Ireland, under Cromwell, it had only been four shillings, while the two surgeon's mates had half-a-crown daily. Financial tightness prevented the maintenance of the high rate of six shillings, and by 1657 it had fallen again to four. General Monck thought that this was too low, and raised it in a way that is characteristic of former times in the services. He put the surgeons on the roll as privates, so that they drew ninepence a day extra. Apparently both surgeons and privates had to feed and often lodge themselves out of their pay.

In Essex's army Dr. St. John was "physician to the train and person" and Laurence Lowe held a like appointment as surgeon. In the list of the staff of the "New Model Army" are the names of four medical officers and the armies in Ireland and Scotland each had a Physician-General, a Surgeon-General and an Apothecary-General, which arrangement was maintained after the Restoration. Dr. Henry Glisson, brother of the great Dr. Francis Glisson was Physician-General to Manchester's army, and he and later Physicians-General to Cromwell and Monck received pay at the rate of ten shillings a day, while the Apothecary-General received six shillings and eightpence a day. When important persons were ill the "mere army doctor" was not trusted alone, but civilians were called in. Thus when Cromwell fell ill in Scotland in 1651, Drs. Wright and Bate were sent down to him and liberally paid by Parliament When the regular army surgeons were not at hand, civilian practitioners were employed and were paid by the job. There is a bill in the Record Office from one of these, a certain George Blagrove, which Mr. Firth quotes. For "curing a sore brused leg" the charge was ten shillings. "Cut over the eye and a sore thrust through the arme, twenty shillings." This bill also includes £5 for curing the inglorouis wounds of twelve cavaliers, of whom most were "sore cut in their heads and thrust in the back."

---

* "Cromwell's Army: A History of the English Soldier During the Civil War, the Commonwealth, and the Protectorate." Being the Ford Lectures delivered in the University of Oxford in 1900-1. By C. H. Firth, M.A. London: Methuen & Co., 1902.

Any systematic attempt to collect and remove the wounded from the field is quite a thing of late years, but in the sixteenth century Diggs, in his Stratiticon (quoted by Mr. Firth), wrote as follows: "It were convenient to appointe certaine carriages and men, of purpose to give their attendance in every skirmishe and incounter to carry away the hurte men to such place as surgions may immediately repayre unto them, whiche shall not only greatly incourage the souldior, but also cause the skirmish to be the better maintained, when the souldiors shal not neede to leave the fielde to carry away their hurte men. These were called among the Romans 'Despotati.' And this among other laudable Romane orders have the Spaniards at this day revived and put in practice, whereby also they conceale from the enemie what losses in any skirmishe they have received."

In the Civil-war the surgeons and men of the victorious army cared for their wounded, and then usually leave was given to the people of the neighborhood to do what they could for the enemy's wounded, who were left on the ground. There were no movable or field hospitals and the injured were removed to any houses near and cared for by the occupants, and claims for this care were made, and were paid by Parliament, some permanent hospitals were established in towns, as at Bristol in 1645 and at Northampton after Naseby. At first the chief or only permanent hospitals were St. Bartholomew's, St. Thomas', and Bethlem in London. Afterward special military hospitals were established in the Savoy, and at Ely House, to accommodate about 350 patients. In Dublin the Archbishop's house and "the mass house in Back Lane" were utilized for sick and wounded, and in Edinburgh Heriot's Hospital, but it provided only thirty beds for an army of 10,000 men or more, though for these thirty the diet provided seems to have been liberal. The nursing in the hospitals was done by women, mostly soldiers' wives or widows; for instance, in the Savoy Hospital, it was ordered that they should be "chosen from the widows of soldiers so far as fit ones can be found." In the two London military hospitals, at Ely House and the Savoy, there were twenty-nine nurses to 350 patients, not an inadequate number, seeing that some of the patients were not very ill. In Edinburgh, the provision was one nurse to five "weak" men, and one per ward "where the patients are ambulant." Nurses were paid from £10 to £13 a year. Whether this included board or no does not appear. Strict regulations were made for the preservation of discipline and decorum, and amongst other rules was one that if a patient and a nurse married, both should be expelled. Not content with instituting hospitals in the capitals for its soldiers, the Council of State in 1652 sent 220 soldiers from Ely House to Bath "for the recovery of their limbs and perfecting their cure."

Apparently some invalids were maintained in the hospitals as well as the sick and wounded who were actually under treatment, but they were not all well cared for. The money difficulties of the Government increased apace, and it appears from a report presented in March, 1660, that the revenues assigned to the hospitals had not been paid for nearly a year, so that the patients were in the greatest distress, "insomuch that some have been starved; others have attempted to destroy themselves; and many are daily likely to perish through imprisonment, hunger, cold and nakedness. And the sick and mained soldiers now under care in the said hospital are also ready to perish for want, being not able to stir out of their beds, and having had no pay these four weeks."

In concluding the chapter Mr. Firth writes; "So closes the history of the long Parliament's effort to provide for the soldiers who suffered in the Civil War. It had promised more than it could perform, but it had made a serious attempt to carry out the principle it had laid down in 1642. It recognized the moral obligation of the State to those who suffered in its service, and it was the first English Government to do so. In 1680 the foundation stone of Kilmainham Hospital for old soldiers in Dublin was laid, and in 1681 that of Chelsea Hospital. Thus at last the example of the Long Parliament bore fruit." France was before England in this respect. The Invalides, founded by Louvois, was opened in 1674.

LYMPHANGIECTASIS.

Notwithstanding the many investigations that have been made by pathologists during recent years, there remain still many unanswered and interesting questions concerning the etiology of lymphangiectasis. The term lymphangiectasis is a broad one, and is considered usually to include only ectasiæ of a subacute or chronic nature.

The etiology of this symptom, for as such we must consider it, in some conditions seems very evident, but in others is very obscure. Its occurrence is frequently attributed to mechanical or obstructive interference to the flow of lymph, more careful observation finds this explanation unsatisfactory and recognizes other etiological factors.

Among the obstructive causes may be mentioned: (1) A contracting scar following an injury in which the lymphatic dilatation may occur weeks after the trauma. (2) The destruction of large areas of lymphatics by suppuration of an entire group of lymphatic glands or by extirpation of the same, or occurring as the result of destruction caused by extensive phlegmon. (3) Direct trauma with extensive maceration of soft structures has also been recognized as a causative factor. Lymphatic dilatation is not rarely due to the presence of tumors, as a result either of pressure by the new growth or of the secondary involvement of the lymphatic glands. With the appearance of an exuberant callus of the forearm, a chronic lymph stasis of the hand has been seen to occur, which subsequently disappeared. Lymphangiectasis following these causes is, however, usually temporary, an equilibrium being later established by means of anastomotic circulation.

Among the intralymphatic causes of this condition must be included inflammatory conditions of the endothelium, resulting in occlusion and obliteration of the lumen, such as follow repeated attacks of lymphangitis or erysipelas. This variety of lymphangiectasis is not infrequently seen involving the upper lip, eyelids, nose, or ear. Complete obstruction in an entire lymphatic district has been seen to occur from primary proliferation of the endothelium. Chronic infectious processes, such as tuberculosis, may so alter the lymphatic channels as to cause a distal lymph stasis. And parasites, the filaria sanguinis of the tropics, by occlusion may cause the same symptom complex.

In view of these facts it might be supposed that a stasis and retension of lymph from mechanical pressure could cause a dilatation of the lymphatic vessels for a time, but in such a rich network of intercommunicating plexuses, a collateral anastomosis would occur in much less time than in the venous circulation. On the other hand, the fact must not be lost sight of that the pressure under which the lymph flows is very much less than that in the veins. Furthermore, according to the experiments of Magendie, Cohnheim, and others, circulatory obstruction to the large trunks in the lymphatic circulation, even ligation of the thoracic duct, is not always followed by an ectasia of distal tributaries, nor, according to Lesser, does lymphangiectasis follow extirpation of the chief lymphatic trunk of an extremity.

For these and other reasons many investigators are of the opinion that the determining etiological factor of lymphangiectasis is in the wall of the lymphatic vessel itself, not a passive but an active process, excited, perhaps, in many instances by a preceding pathological condition.

Whitehead contributes an exhaustive discussion on this subject to the *British Medical Journal* of March 29 and May 3, 1902. The first case of his series was one of molluscum fibrosum of huge dimensions, in which the entire arm from the wrist to the shoulder was involved in the tumor. This huge mass was elephantoid throughout, the lymphatic œdema being limited, however, to the growth and in no way affecting the hand. In the author's opinion we need not look beyond the growth itself in our search for the causes of the lymphangiectasis, and he explains the lymphatic distension either by an obstruction in the lymphatic vessels draining the growth or by an increased rate of lymph secretion.

Furthermore, it is probable that the retarded outflow of lymph, either to its own presence or from irritating characters it may assume upon stasis, causes an overgrowth of the subcutaneous elements, and more particularly of connective tissue, and so itself becomes responsible for the elephantoid overgrowth.

THE SERUM TREATMENT OF ACUTE AND CHRONIC ARTICULAR RHEUMATISM.

The salicylates are useful, indeed indispensable, remedies in the treatment of rheumatism, but they are not the absolutely certain specifics that it was hoped they would prove to be when they first came into notice. Even when they seem to exert a curative effect, convalescence is apt to be prolonged, and the patient gets up from his bed far from a well man. It is natural, therefore, that a watch should still be kept for other and more satisfactory methods of treatment, and since the belief has become so general that rheumatism is a germ disease, the hope has arisen that a specific serum might be obtained which would supply the defects of salicylic acid.

Menzer, in an article in the *Zeitschrift fur Diatetische und Physikalische Therapie*, Vol. VI., No. 4, ascribes favorable results in the treatment of these cases to the injection of a streptococcus serum especially prepared for the purpose. The cultures obtained from the tonsils of rheumatics are not attenuated by passage through animals and then used for the immunization of larger animals, but are kept, as nearly as possible, in their original form by cultivation on ascites fluid to preserve their virulence, and then are injected, in graduated doses, into larger animals. The serum thus prepared is not antitoxic, but antibacterial, and its introduction into the body supplies the latter with bacteriolytic agents. The injection of the serum, therefore, reinforces the natural reactive process of the body. Its action at first is to increase the inflammation and temperature, but later it facilitates defervescence, and in the healthy produces no reaction whatever. Its use in twenty cases showed that it was without effect in diminishing pain or fever, or modifying the usual clinical sequence of events, but as soon as defervescence occurred the patients were fully convalescent and no relapses were observed. The duration of the fever averaged five or six days; that of the temperature, six or seven days, and the first day out of bed was usually the fourteenth. Chronic cases, in particular those that had already resisted the salicylates and other methods of treatment, were cured, or greatly benefited in from two to three weeks. No untoward by-effects were observed, except slight redness at the site of injection and occasional swelling of the adjoining glands.

Bolo Wounds.

Among the novelties which the acquisition of the Philippines have brought to our notice one of the least desirable in its effects is the bolo, the weapon of the native Tagalog. This is an ugly sort of a knife, varying in size and shape among different tribes, some resembling the machete or cutlass of the West Indies, others being long, straight, and sharp pointed, with a single or double cutting edge. The weapon is not so effective as a Winchester at long range, but in close encounters it inflicts some ugly wounds.

In the *Journal of the Association of Military Surgeons* for August, Dr. Carl de Wolf Brownell, U. S. N., relates his experience with ten cases of bolo wounds in Spanish soldiers and sailors under treatment at the native hospital in Cavite. The wounds were all of the upper part of the body. Six of the men had scalp wounds, one a wound of the scalp and side, one of the forehead and forearm, one of the forearm alone, and one had suffered a clean amputation of the corpus. All except the puncture in the side and the amputation were simple incised wounds, but long and deep. But two required operative interference: (1) In the case of the amputated hand, it was necessary to sacrifice the lower extremities of the radius and ulna to obtain flaps. (2) The wound of the right forearm resulted in a secondary hemorrhage from the radial artery calling for ligation.

Before coming to the hospital, formerly a convent, these patients had been from one to four days without treatment, and the conditions at the hospital were most unfavorable. There were not enough cots for the patients, and many had to lie on the bare floor; the wards were filthy, overcrowded, and ill-ventilated; the food consisted of a meager allowance of rice with a little boiled beef; the dressings were unclean and infrequently changed. As might have been expected, all of these wounds suppurated; yet all of the patients ultimately made good recoveries. None of the wounds, with the exception of the amputation at the wrist, would have been at all serious, if properly dressed at first.

Dr. Brownell makes the further observation, of general though not of medical interest, that, to offset the eleven Spaniards with bolo wounds, there was not one Filipino among those in the hospital with a bayonet wound; and the suspicion may be entertained that these wounds were inflicted after surrender and not during an engagement.

The Pathogenesis of Gastric Hemorrhage.

The hæmatemesis that occurs as a symptom of gastric ulcer or cancer needs no explanation, and neither does that resulting from portal obstruction, but many cases are met with in which ingenuity and imagination of the clinician are sorely taxed to find a rational explanation of the bleeding. The report, by Nitzsche (*Deutsche Zeitschrift fur Chirurgie*, June, 1902), of a case of gastric hemorrhage occurring in appendicitis seems to throw light on the pathogenesis of some of these instances.

Nitzsche's patient was a man of sixty-two years, who, after having for several years had symptoms of chronic appendical disease, finally developed an acute attack with gangrene of the appendix, abscess, and general peritonitis. When first seen the condition was already too advanced to permit of operation, and the patient's prostration was further increased by the vomiting of large amounts of fresh blood. The autopsy confirmed the diagnosis of the abdominal condition, and the stomach was was subjected to careful study to determine the cause of the hæmatemesis. Numerous miliary necroses of the mucous membrane were found which had evidently been produced to a great extent by the autodigestive action of the gastric juice, and had caused sufficient destruction of the capillaries and venules to permit the massive loss of blood described. The author's interpretation of the affair is that the products of absorpton from the purulent and necrotic foci in the abdomen were carried to the stomach either through the general circulation or else by retrograde transmission through the omental veins. These septic matters were taken up and excreted by the gastric cells, as is usual with most poisons, but some of the cells succumbed to the intensely toxic nature of the poisons passing through the epithelial layer, and minute necroses were formed. These, in turn, were at once attacked by the gastric juice, and larger ulcerations, with their attendant hemorrhage, were produced.

The case is an unusual one, but affords an explanation that no doubt is applicable to many of these cases of hæmatemesis of obscure etiology.

A Congress to Repress the White-Slave Trade.

A congress is to be held in October at Frankfort to consider the best means of suppressing the international traffic in women, which has attained proportions that are appalling. The *Commercial Advertiser* says that a preliminary meeting took place at Paris not long ago, and the facts brought to light proved to be so horrifying as to make the advisability of joint governmental action extremely plain.

For obvious reasons, the particulars of this traffic have not been generally made public yet enough has become known to justify the strongest measures for its abolition. The *Frankfurter Zeitung* says that this trade in women has become as well recognized and as thoroughly organized as was the trade in negroes a century ago. It has its agents, its centers of distribution, and its exchanges. In fact, the *Commercial Advertiser* adds, it has cast a network of systematized infamy over the civilized world, and apparently there is nothing save concerted action on the part of the different governments that can destroy it.

It is not clear why Frankfort has been selected as the meeting place of the congress. Brussels has had several congresses this summer, one on the prevention of venereal disease; and if this congress for the suppression of traffic in women were held in Brussels, under the patronage of the King of Belgium, it would at least be near a source of much potential information on the subject of its discussions.

News of the Week.

Health Matters in the Philippines.—The efforts of the Medical Department of the Army have resulted in a great diminution in the prevalence of dysentery which is one of the scourges of the islands. The enforcement of strict sanitary measures, including the boiling of all drinking water, rules for bathing, and especially the washing of the hands before handling food, has caused the disease almost to disappear. In dealing with cholera, however, the health department of the islands has had a much harder task. There is not only the soldiers to reckon with, who are under discipline and can be forced to observe hygienic rules, but the entire mass of ignorant and superstitious natives and Chinese must be made to conform to the sanitary regulations. The health service of the Manila Government is overwhelmed with the work that has fallen upon it, and the health officials in all the interior towns are in the same plight. The epidemic is not confined to the low country towns, but has been under headway in Dagupan and the mountain towns north of there for a month. The number of deaths in the provinces ranges from 350 to 450 daily. There are on an average from fifty to seventy new cases daily in Manila, and nearly as many deaths. Part of the difficulty arises from the superstitious idea of the natives who believe the disease is a visitation from heaven, and not to be resisted. It has several times happened that bodies of men and women who have died of cholera have been concealed by the natives for several days before the health authorities have found them. Another difficulty in contending with the epidemic is the inefficiency of the Filipino doctors. When working under Americans they are useful, but independently they soon fail. They will not carry out instructions and connive with the natives to conceal new cases. The latest reports being the unwelcome news that the disease is increasing. Three hundred and forty cases were reported outside of Manila on the last day of August, and the totals reported up to that date were 27,929 cases and 19,640 deaths from the disease. All transports leaving Manila for the United States are kept in quarantine in the harbor five days before being allowed to sail.

Food of the City Poor.—In the second quarterly report of the New York Commissioner of Public Charities, recently made public, Mr. Homer Folks says that during the last year of the former municipal administration the diet furnished to the inmates of the almshouse was reduced greatly below the amount required for the nourishment of the aged and sick. The breakfast consisted solely of bread and coffee, and the supper of bread and tea throughout the year. But there is now provided in addition for the breakfast and supper, a half-ounce of butter daily for each inmate, a half-ounce of syrup daily for each inmate, two ounces of oatmeal or rice on Saturday mornings and one ounce of prunes on Sunday afternoons. The dinner remains as before, except that the quantity has been increased.

Sanatorium for Consumptives at Lisbon.—It is stated that the Queen of Portugal has recently given $20,000 for establishing a hospital for tuberculosis near Lisbon.

Large Bequests to Charity.—The late Mrs. Katherine Barron Aultman of Canton, Ohio, bequeathed by her will $327,000 of her estate, valued at $350,000, for charitable and benevolent purposes. She gave $100,000 to the Aultman Hospital in Canton and $100,000 for the establishment in the same town of a home for aged, indigent women.

Accidental Death in a Private Hospital.—A woman patient in a private hospital in this city was killed one afternoon last week by falling down the elevator shaft. She had been etherized preparatory to operation for pelvic disease, and was being taken in the elevator to the operating room on an upper floor when, by a strange mischance, her cot was tipped out as the elevator was passing a landing where the door was open, and, as the car continued to ascend, fell back and down the elevator shaft, when the woman's skull was fractured.

Reform at the Morgue.—The management of the morgue in this city has been reorganized by the Commissioner of Public Charities, in order to prevent mistakes which have occurred from time to time in the past in the delivery of bodies, and also to prevent scandalous collision on the part of the employees with rapacious undertakers. It frequently happened that one of a small group of undertakers, learning from some employee of the department of the death of a patient, would call on the relatives, secure the death certificate through misrepresentation or through ignorance on their part that they were authorizing him to take charge of the body, and then take charge of the remains and either insist on conducting the funeral or extort a payment for "services" already rendered.

Board Accommodations for the Madrid Congress.—An office has been opened at Madrid to secure accommodation for members who propose to attend the Fourteenth International Congress of Medicine which will be held next April. Applications should be made direct to the secretary, Bureau des Logements, Faculté de Médecine, Madrid. Intending visitors to Madrid should not delay too long in making application, for if the attendance is as large as is now anticipated there will hardly be sufficient accommodation for all.

Arrest for Not Reporting Smallpox.—The health officials in Brooklyn are proceeding against physicians in that borough who fail to report to the Board of Health all cases of notifiable contagious diseases occurring in their practice. One physician was arrested last week on a charge that he had failed to report several cases of smallpox which he had been treating. The accused pleaded not guilty but was held for trial.

The Health of Virchow is reported to be in a precarious condition. He was at Harzburg in the Harz Mountains until last Sunday, when he was removed to Berlin. No one except the members of his family and the doctors have been allowed to see him for several weeks. It was believed until quite recently that he was making satisfactory progress toward recovery, but the *Deutsche medicinische Wochenschrift* of last week announced, on information obtained from the physicians who are treating him, that the improvement of the week before had not been maintained and that his strength was unmistakably failing. But his interest in human affairs shows no abatement, and only a few days ago he accepted the offer of the honorary presidency of the new German Society for the Exploration of Anatolia.

A Medical Candidate for Governor of California.—Dr. George C. Pardee of Alameda was nominated for Governor of California by the Republican State Convention in Sacramento on August 27. Dr. Pardee is an ophthalmologist, a graduate of the University of Leipsic in 1885. Possibly, if he is elected, he will be able to recognize the cases of plague occurring in Chinatown of San Francisco, to the existence of which the authorities have until now so obstinately closed their eyes.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy, week ending August 30, 1902: August 22.—P. A. Surgeon W. H. Bell detached from the *Chesapeake* and ordered to duty as a member and recorder of a board of medical officers Naval Academy, Annapolis, Md., thence home to wait orders. August 26.—P. A. Surgeon F. L. Benton, part of order of May 27, detaching from *Columbia*, revoked.

Stony Wold Sanatorium.—The cornerstone of the Stony Wold Sanatorium at Lake Kushaqua is to be laid early in September, when a number of the officers, directors, and members of the various auxiliaries of the charity will be in the Adirondacks to attend the ceremony. The foundations of the main building of the sanatorium and one dormitory are almost completed, and work on the upper stories will begin shortly. The institution is in an ideal spot. The buildings are near enough to the station to be seen from the trains, and are situated on a beautiful lake surrounded by mountains and woods of pine, balsam, and fir. A number of entertainments given at Loon Lake, Big Moose, and elsewhere in the Adirondacks this summer added several hundred dollars to the building fund.

Decline in the British Birth Rate.—According to figures recently published in London, France is not the only country in which the birth rate is below the normal. The statistics show also a marked decline in the English birth rate. London shows a decrease since 1881 from 27.4 to 20.6 per 100 of married women under the age of forty-five years. The decline is most noticeable in the fashionable quarters of the capital, while the slum areas, such as Stepney, Shadwell, and Bethnal Green, are almost stationary. Outside of London the decline amounts to 25.8, against 30.3 in 1891.

Contest over Possession of a Hospital.—The Mayor and the Board of Health of Jersey City are struggling for the control of the City Hospital. This hospital has always been under control of the Health Board, which is also the Police Board. But last winter the State Legislature passed an act creating a Board of Trustees, and authorized these Trustees, who were to be appointed by Mayor Fagan, to take possession of the hospital and also of the funds set apart for its maintenance. Dr. McGill of the Board of Health opposed the transfer on the ground that the act creating the Trustees was unconstitutional, because it only applied to Jersey City. A few days ago he obtained from Justice Collins a rule to show cause why a writ of certiorari should not issue, restraining the Mayor and the Board of City Hospital Trustees from taking possession of the hospital. Despite the notice that the rule had been granted. the Mayor and the Trustees took possession of the hospital on Thursday of last week, but reconsidered their action on the following day and returned the hospital to the control of the Health Board. The Supreme Court will review the acts of the city authorities in the premises some time this month.

New Physical Culture School for Teachers' College.—Plans have been filed with the Building Bureau by Parish & Schroeder, architects, for a new physical culture school for the Teachers' College of Columbia University. The new building will be five stories with basement and an attic. In the basement will be several hand-ball courts, bowling alleys, and a large swimming tank. The first story will contain a lecture room, reading and seminary rooms, and the laboratory and a large reception parlor. Class rooms and exercising parlors for men and boys will occupy the second story, and the third story will have exercising rooms and bathing rooms for women and girls. The fourth and fifth floors will be devoted to the big gymnasium, and in an attic story will be fencing rooms with galleries for spectators. The building is to cost $200,000.

A Strike of Trained Nurses.—Twenty-four of the thirty-five trained nurses employed at the Worcester, Mass., Insane Asylum have struck for shorter hours and because they did not like the treatment accorded them by the Superintendent. The trouble is not of recent origin, but has been brewing for many months. The nurses say that they are obliged to be on duty more than twelve of the twenty-four hours every day, and that they have but eight hours off duty during the week.

Notification of Malaria.—The Board of Health has prepared a circular to be sent to practitioners in this city, requesting them to report to the board all cases of malarial fever under their care. "It is the earnest desire of the Department of Health," this circular reads, "to acquire all possible information as to the occurrence and distribution of malaria in New York City, with a view to its eventual stamping out, and physicians are therefore requested to notify the department of all cases of malarial fever coming under their observation. Information is desired regarding the location of the fever, so that, as far as possible, proper measures may be taken to correct the insanitary conditions which produce it." No facilitate the desired notification of malaria, special postal cards have been prepared, and a supply of these cards will be sent to any physician on request. In return for such co-operation on the part of physicians, the Department of Health will make free microscopical examinations of the blood for malarial parasites, whenever requested to do so by the physician in attendance on a suspected case.

Fire in a Hospital.—A blaze was started last Saturday, in the New York Infirmary for Women and Children, by the ignition of some gauze that was being sterilized, but, by the presence of mind of the nurses, a panic among the patients was averted. The nurses were notified and were sent to their stations, but the fire was extinguished before any of the patients learned of the accident.

Typhoid Fever is prevailing to an unusual extent in several cities of the country. Washington and Chicago being among the most afflicted. In the former city there were over 250 cases of the disease the last week in August, and in Chicago 129 deaths from typhoid fever occurred during the first three weeks of that month.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HEALTH—THE HOSPITAL FUNDS—YEOMANRY HOSPITALS—LATIN FOR PRELIMINARY EDUCATION—DEMAND FOR M.D.'S—VACCINATION LEAGUE—ANOTHER TROPICAL EXPEDITION—CANCER FUND—COST OF LONDON LUNATICS.

LONDON, August 15, 1902.

The coronation completed, the final bulletin appeared on Sunday morning just to say his Majesty bore the strain perfectly well, experienced but little fatigue, and had passed a good night. The King and Queen drove to the thanksgiving service on Sunday morning. As if to emphasize his recovery and complete fitness for work, the King resumed on Monday his royal duties to the full extent. Audiences, privy councils, investitures, reviews, and so on succeeded each other and occupied much of his Majesty's time until yesterday when he returned to Cowes and, as if to show himself as well as ever, immediately paid a visit to the Empress Eugenie on board her yacht.

Among the early functions of the week the King received the Lord Mayor, Viscount Dungannon, and Sir Savile Crossley, who presented the coronation gift of £115,000 subscribed by all classes, including nearly 20,000 donations from the working class—mostly in pence. They stated that there would be a further balance on closing the accounts, and that increased support, had also been secured in this coronation year for King Edward's Hospital Fund as well as for the Sunday and Saturday Funds.

The King expressed his pleasure that the gift embraced offerings from poor as well as rich, and his great gratification that progress had been made this year toward the attainment of his object in originating the fund; that object was to free the London Hospital from debt. His Majesty then handed the gift to the Prince of Wales, President of the fund, to be applied to its augmentation.

The report of the Council of the Sunday Fund was presented on the 5th inst. The income to date was £59,000, and the Lord Mayor anticipated that before the financial year closes (October 30) the total will surpass any previous year. It was agreed to distribute £57,800 between 204 institutions—four more than last year. The Lord Mayor called attention to the recommendation of the committee that no part of the grants should be spent on bricks and mortar. He said that a large proportion of the money was subscribed by the poorer class, and they, naturally, expected it to be spent on the patients themselves.

Monday was a red-letter day for all connected with the Yeomanry Hospitals which did such good service in South Africa. The Queen, who was accompanied by several of the royal family, distributed the war medals It took about an hour to do this, for there were more than thirty surgeons, forty nurses, and some 200 of the hospital staff. The presentation was made in the garden of Devonshire House, where the Duke afterward provided refreshments for the recipients and other visitors.

You would scarcely anticipate any difference of opinion on the queston of Latin being retained as a subject of preliminary education in so ancient a corporation as the Royal College of Physicians, which still calls its meeting a comitia. Still less would you expect to find Fellows of the venerable college ready to bow in this matter to the newly-organized university, which has at present had time to do nothing except pass some resolutions—one of which, as I have already informed you, is to make Latin optional—yet both these unexpected things occurred at the last comitia.

A resolution was brought forward that it is desirable Latin should continue to form part of the medical student's preliminary education The action of the university senate was dealt with gently, and the special value of Latin for medical men, as well as its importance as an intellectual disciplin, and the broadening influence of a knowledge of a previous civilization were shown. The college was urged to set the example of a high standard in the matter. Thereupon opposition was expressed Dr. F. Taylor admitted all that had been said in favor of Latin, and then, by a remarkable *non sequitur*, said the decision of the university senate was well-advised, because of the special fitness of the university to decide what are the proper subjects for preliminary education. The colleges, he declared, are not in so good a position to determine matters of this kind. He then moved to proceed to the next business, a proposal seconded by Dr Norman Moore, but not at once adopted, and the discussion was adjourned.

If Latin is to be banished by the reorganized university as effectively as Greek was before its reconstitution, we may, perhaps, look forward to a time when pharmacists may offer us lessons in writing prescriptions as freely as they have been doing in therapeutics.

The petition of the Licentiate, and members of the two Royal colleges who desire the opportunity of obtaining a university degree, has been referred to a conjoint committee of the two colleges recently authorized to consider the possibility of a connection with the London University for certain purposes.

The Imperial Vaccination League, the formation of which I announced to you, has begun its work with an appeal for the necessary funds. Its object is to get the country protected against epidemic smallpox as thoroughly as Germany is. The Duke of Fife is President.

The Liverpool School of Tropical Medicine is sending out yet another expedition—the eighth. It will start on the 23d inst. under Drs. Dutton and Todd for the Gambia and French Senegal.

Toward the £100,000 required for the Cancer Research Fund, £35,000 has already been obtained.

Increase of cost of metropolitan lunatics, together with a decrease in their number, is being commented on. The excess is attributed to an increase of the staff, and people ask why increase of staff should coincide with decrease of patients. Augumented salaries in these circumstances also give rise to questions.

Progress of Medical Science.

The Boston Medical and Surgical Journal, August 28, 1902.

Cases of Prostatectomy, with Remarks on the Operation.—Paul Thorndike reports nine cases with but one death. Of the eight cases which survived the operation, six were cured, a cure meaning the complete removal of all obstructing tissue, practically no residual urine, and comfort of the patient. The writer formulates his conditions founded on a study of these cases, as follows:

(1) Great relief can be given to all patients suffering from symptoms due to obstructing enlargements of the prostate, either by palliative or by operative means. (2) The time to resort to operative measures is just as soon as palliative treatment, carefully executed by competent hands, has failed to give relief; (3) Complete prostatectomy is always the operation of choice, because it is the only operative procedure which cures or gives *uniformly* good results, when successfully performed in proper cases; (4) The best time for its performance is just as soon as palliative efforts have failed, or are manifestly impossible of execution, and before secondary changes in the bladder and kidneys, due to long-continued obstruction, have taken place; (5) In those cases which come for surgical relief so late in the development of the pathological conditions that the bladders and kidneys are extensively diseased, and the patient is manifestly exhausted by long-continued suffering, other less certain and perhaps less severe measures may be advised, instead of a complete prostatectomy; but such a decision can only be and must always be made by the surgeon for the individual case, and cannot be made the subject of a generalization.

Smallpox; Its Medical Treatment.—Michael Kelly says that smallpox is a disease which affects the entire system, and the physician's duties in regard to it are, therefore, many and varied. For the treatment of those in whom the disease is diagnosed an isolation hospital is the proper place, but it should be a retreat in which the physician himself would willingly be confined if necessary, or to which he would send a member of his family. Smallpox patients are not criminals or outcasts, and should not be treated as such. Strong, ambitious, trained nurses, recently vaccinated, and not afraid of the disease, should be secured if possible, as the nursing required is too laborious for delicate or timid nurses. No special treatment is indicated for the incubation period, except to prevent patients from doing anything which might debilitate them for the disease about to develop; the author has made one or two attempts to modify the disease by vaccination at this stage, with apparently some benefit, but the cases so treated are too few for any general conclusions to be based on them. In the stage of invasion, on the tenth to the fifteenth day of the incubation period, rest in bed is indicated. An abundance of fresh air is absolutely necessary in keeping down the mortality. The temperature of the room should not be above 70° or much below 60°. Solar light should be excluded as completely as possible, since it is reasonably certain that its access to the face is largely productive of the pitting left after severe cases. Inexpensive dark window curtains will serve this purpose. The headache, backache, and other distressing symptoms of this stage yield readily to four or five grains of phenacetin in a little sherry or brandy, and repeated every two or three hours as indicated. The same formula, supplemented by moderate doses of the bromides and chloral, is useful for the fever and delirium accompanying the period of postulation and suppuration. Gastric irritability is relieved by sucking small pieces of cracked ice or by small sips of iced lemonade. Poultices or hot water applications to the stomach or back should not be used, as they make the effects of the oncoming eruption more marked and lasting. Smallpox is a profoundly exhausting disease, and tonics are indicated at this stage and throughout its entire course. Only easily digestible, yet nutritious, food should be offered. Milk, eggs, animal broths, and an abundance of pure cold water or lemonade are acceptable. Mild laxatives may be given in the early stage, and continued at intervals throughout the course of the disease. Stimulants are useful additions to the sustaining treatment at any period. The pain and tension in the skin, and the itching which develops as the eruption becomes vesicular and pustular, can be relieved by the application to the parts of cloths wrung out of cold or hot water, according to the patient's choice, and often changed, as it is evidently the moisture which produces the soothing effect. As this stage advances, the nose, mouth, soft palate, and throat suffer from the eruption, and gargles of chlorate of potash give marked relief, or even better is a careful rinsing of the mouth by the nurse with a piece of clean linen dipped in a 1 to 20-per cent. solution of boric acid. A saturated solution of boric acid in rose water is most grateful sprayed from an atomizer over any afflicted part of the body. The intense itching is relieved by a mixture of olive oil and lime water, to which a little carbolic acid or thymoline is added. At the height of the secondary fever, when the patients are too sore to stand immersion baths, daily bichloride sponge baths may be given. The writer had success in one case from the use of antistreptococcus serum, by means of which he was enabled to tide the patient over the dangerous time of rupture and desiccation of the pustules. The case was an unusually severe one of confluent smallpox. On the eleventh day of the eruption, and therefore two or three days before rupture and desiccation of the pustules, the patient had an evening temperature of 105.5° F. The face, arms, forearms, hands, legs and feet were intensely swollen and œdematous, and the patient was profoundly apathetic. The writer injected subcutaneously, under strict antiseptic conditions, into the tissues of the back 10 cc. of antistreptococcus serum; two similar injections at intervals of twenty-four hours were made into the forearm and thigh respectively. In about twelve hours after the first injection the œdema about the eyelids began to subside, and the patient could move his eyelashes; a similar change took place about the mouth, and the profound apathy rapidly abated. The breathing and pulse also improved. In a few hours after the last injection the morning temperature was normal. It was fully sixteen days later, however, before the patient ceased to have an afternoon temperature of a degree or a degree and a half. He finally made a good recovery, and developed no abscesses nor sores at any time. After the suppuration and secondary fever have subsided, the patient should receive two or three antiseptic baths at intervals of twenty-four hours. He is then freshly dressed and removed to an uninfected part of the building, or, if the weather will permit, to a tent outside the grounds, where the antiseptic bathing is continued for three days more. Although varioloid occasions very little suffering in itself, and rarely calls for more than a day or two in bed, the laws of quarantine, disinfection, and fumigation should be as strictly enforced as in smallpox, as the disease may be spread in its worst form from a case of simple varioloid.

Journal of the American Medical Association, Aug. 30, 1902.

General Nervous [Manifestations in Relation to the Jaws and Teeth.—George V. I. Brown considers that the habit of grinding and clenching of the teeth, a hyperkinetic condition of the muscles of mastication, may in some instances be an etiological factor in functional nervous disorders or, more often, perhaps only a symptom. One of the simplest means of relief, in such cases, is the application of a hard rubber plate, with soft velum rubber border, extending over the occlusal surface of the teeth. The palatal portion gives a sense of firmness and security, and the soft rubber covering to the crowns of the teeth makes grinding or serious injury by undue irritation impossible. It need only be worn at night, and thus gives very little serious inconvenience to the patient if carefully adjusted. He reports nine cases showing the advantage of the method of treatment practised by him.

A Subsequent Report of a Case of Carcinoma Discharged as Hopeless and Reported as a Failure.—William Allen Pusey refers to a case, published five months ago, of extensive carcinoma, involving all the structures in and around the right orbit. It was exposed to the action of the *x*-rays, but the treatment was discontinued during the second month because the tumor increased and excruciating localized headaches, as well as acute inflammation of the whole involved area, appeared. Five months later, however, it was found that the mass that had occupied the orbit had shrunken, allowing the lids to close. There were a few small nodules on the nose near the inner canthus, but otherwise the patient was in excellent condition. The case shows that the effects produced by the *x*-rays persisted for months after discontinuance of treatment, and were sufficient to cause the disappearance of a tumor, and at least the symptomatic relief of a case which upon the basis of all experience could end only in death within a short time.

Oral Hygiene.—George F. Eames discusses the methods that he considers best adapted to produce a healthy condition of the mouth and teeth. The patient on rising should rinse the mouth several times with water and follow this by brushing the teeth for three minutes, using brushes, powder and washes selected by the dentist. The teeth should be brushed in all directions, including a rotary motion, with the object always of removing any foreign substances clinging to their surfaces. The brush should be wet with an antiseptic wash, and plenty of powder should be used. The gums should also be brushed, but for this purpose a brush with rubber bristles is best, using it wet either with an antiseptic wash or with vaselin. ℥i, menthol grs. iii. If the condition of the mouth requires it, the gums may also be rubbed with the tips of the fingers on which this preparation has been placed. Besides toothpicks, to be used after meals, the patient may resort to the stick and pumice. The tongue is to be cleansed, when necessary, by means of a brush with rubber bristles, but never with the stiff hair bristles which have been used for cleansing the teeth. When the breath is impure and the cause is not to be found in the teeth and surrounding parts, the tonsils should be inspected, and if pockets exist in the faucial tonsils, they should be cauterized and the organs reduced in size, if necessary. If adenoids are present, they should be removed. The nose should also be examined, and polypi or catarrhal conditions should be treated. Inflamed gums are treated by douches of various forms which conduct water at a temperature of 110°F. to the mouth. Such douches have been devised by the author.

The Medical News, August 30, 1902.

Suture of the Solid Viscera.—In considering this subject the writer, R. C. Coffey, refers especially to the liver, but the same principles apply to the spleen and kidney. He describes his method as follows: Two sutures are used; one being applicable to an incision which does not penetrate the liver entirely, and the other is applicable to wounds in which the liver is severed through and through. One he calls the *Y*-suture and the other the *X*-suture. The *Y*-suture is placed as follows: A round, curved needle, at least four inches long, armed with catgut or silk, is passed through the catgut support to the bottom of the incision, comes out on the other side, passes through another catgut support, re-enters through the support of the same side, goes back parallel to the other stitch and comes out through the support from which we started, making a quilt suture. A suture is then passed from the opposite side of the liver, either straight through or indirectly, as may be convenient, includes the two threads at the bottom of the cut in its loop, comes out on the bottom of the liver and again both ends passing through a single catgut weave are tied in the form of a quilt suture, thus drawing the other suture well into the bottom of the cut. The first suture is now tied, and any amount of pressure can be used, for the line of pressure is not against the suture, but is upon the catgut supports. Thus the bottom of the wound is brought in absolute apposition, and any amount of pressure desired may be used. This may not bring the surface of the liver in as close contact as is desired, therefore, a second quilt suture is passed through the edges of the support, nearest the wound, simply taking in the capsule. In this way the tissues are absolutely brought in contact, and as much pressure can be brought to bear in closing a wound of the liver as in any other part of the body. In closing a wound of the liver which extends entirely through its substance, a modification must be used. Instead of the single suture which goes into the bottom of the liver, a second quilt stitch is passed through both sides on the bottom, the same as the *Y*-suture above, interlocking the two sutures to the center of the wound. In this way the pressure is brought to bear in a very effectual manner. For the benefit of those who are working along this line, the writer suggests that the needle should be round, full-curved, and fully four inches long, while the counter-stitch may be made with a simple darning-needle or any kind of a long straight needle.

The Complications and Sequelæ of Acute Croupous Pneumonia.—After an exhaustive review of the literature of this subject, the authors, H. A. Hare and Arthur Dare, came to the conclusion that the complications and sequelæ of croupous pneumonia, independent of the cases due to mechanical causes, are best studied and classified as pneumococcic infections. Pathology has not aided us in discriminating as to whether the complicating conditions which are detailed occur primarily with the initial invasion of the organism, or whether we are confronted with a general re-infection dependent upon blood contamination with the pneumococcus. In studying these complications and sequelæ, the authors group them into certain classes and divisions and present them in a tabular form that makes them easily remembered. The series is composed of six classes, as follows. The first class is made up of the serous membranes:

Class A.

Serous membranes	Pericardium	Serous and purulent pericarditis.
	Pleura	Serous and purulent pleuritis and that affecting the diaphragmatic pleura.
	Endocardium	Endocarditis. Malignant endocarditis. Ulcerative endocarditis, endocarditis, with or without meningitis, or cerebrospinal meningitis.
	Synovial membranes	Serous arthritis. Purulent arthritis. Osteoarthritis.

The infection by the pneumococcus may cause pathological changes in the central nervous system by the action of the toxins on the nerve centers.

Class B.

(*a*) Cerebral and cerebrospinal system . .	Cerebral pneumonia. Meningitis. Meningitis due to pressure of exudate. Cerebrospinal meningitis. Hemiplegia. Paralysis. Cerebral abscess. Aphasia.
(*b*) Toxic action on the Nerve centers.	Delirium. Mania. Convulsions. Cardiac asthenia, resulting in delayed resolution, abscess and gangrene. Brachial neuritis. Bilateral polyneuritis. Trophic disturbances (herpes zoster). Temperature disturbances (hyperpyrexia) (subnormal ranges). Albuminuria and nephritis.
(*c*) Neurotic tendencies	Retention of urine. Tetanoid and choreiform phenomena.

Changes in the blood and intravascular formations.

Class C.

(*a*) Intravascular (thrombosis and embolism)..........	Pulmonary gangrene, abscess and bronchiectasis. Spontaneous gangrene of lower extremities. Embolism of right lenticulo-optic arteries. Phlegmasia alba dolens. Renal and splenic emboli. Embolism of the brachial veins.
(*b*) Hemic changes . . .	Purpura hæmorrhagica. Hæmoglobinuria.

Class D.

Infection of glands and glandular structures	Parotitis. Suppurative parotitis. Bronchial adenitis. Submaxillary adenitis. Thyroiditis. Orchitis. Ovaritis and abscess. Hepatitis.

Class E.

Infection of middle ear	Otitis media Purulent otitis media.

Class F.

From mechanical interference..........	Œdematous laryngitis. Fatty tumor of right auricle. Jaundice, from obstruction of the bile-ducts. Dilatation of right heart from pulmonary obstructions (?) or toxic myocarditis. Delayed resolution and induration from cardiac asthenia.

Pulmonary Syphilis.—James M. Winfield says that, reasoning from the conflicting opinions of physicians, there seems but little doubt that syphilis does invade the lungs almost as often as it does the other viscera, and that the reasons why evidences of it are so seldom found are perhaps: (1) The difficulty in differentiating it physically from tuberculous phthisis; (2) The possibility of syphilis and tuberculosis co-existing; and (3) The complete cure of the syphilitic lung lesion. He recapitulates the symptoms as follows: The disease is more often seen in females; bronchial catarrh; dyspnœa, often distressing; scanty and blood-stained expectoration, becoming profuse and purulent as the disease progresses; sputum never contains tubercle bacillus; pain is referred to the scapular region and can be aggravated by pressure over the sternum; night sweats uncommon; little, if any, elevation of temperature; emaciation not a prominent feature; the presence of periosteal thickening of the clavicle; signs of bronchial stenosis; consolidation and cavity formation. The writer then reports the case of a woman who after a long sojourn in the mountains and every kind of treatment for tuberculosis, including injections of antituberculous serum, was finally cured by vigorous antisyphilitic treatment. The correct diagnosis in this case was finally arrived at by bacteriological examination of the sputum and failure to find any evidences of the pathognomonic germs of consumption.

New York Medical Journal, August 30, 1902.

Nutritive Infusions.—Southgate Leigh describes a plan he has devised of injecting nutriment into the circulation. To be injected under the skin, the food must be sterile, nutritious, easily absorbed, and liquified; easily obtained and readily prepared. These requirements are met by a saline solution of egg albumen. The implements necessary are a simple infusion apparatus, consisting of a glass funnel with rubber tubing attached, a large aspirating needle at the end of the tubing, and a bottle of saline tablets, the formula of which is given.

A Successful Late Laparotomy for Gunshot Wound of the Intestine; Remarks on Suturing.—W. J. Pettus reports a case the interesting points of which were the length of time that elapsed between the receipt of the wound and the operation, thirty-one hours; also the almost entire absence of shock after such a serious injury. The perforations in the intestines were so large and ragged that their closure by suturing the edges parallel to the longitudinal direction of the gut would have seriously impaired the caliber, so they were sutured transversely, as recommended by Mikulicz and Heineke.

The Administration of Chloroform and Ether.—Helen Hughes discusses the relative advantages of chloroform and ether as general anæsthetics, the methods of inducing anæsthesia, the accidents liable to occur, and the treatment to be adopted in such cases. In man the seat of greatest danger is, with chloroform, in the heart, and with ether, in the respiration. In all cases where there is no contraindication the bulk of testimony is in favor of ether, but there are occasions where the life of the patient depends on the proper selection of the anæsthetic. A patient may have a heart that indicates chloroform, but the respiratory organs may be in such a condition that it becomes a matter of choice between two evils, or a weak heart may be accompanied by diseased kidney, making ether nephritis to be feared. Atheromatous vessels may preclude the use of ether where other conditions call for it. This latter condition is one in which chloroform can be used in the first stage and the narcosis continued with ether.

The Education and Development of Neurotic Children.—Graeme M. Hammond believes that the neurotic predisposition can be effectually eradicated by a proper course of physical training, conjoined with proper hygienic surroundings. With careful attention to the diet, sleep, various bodily functions, fresh air, and proper clothing, in addition to systematic and long-continued physical culture, there should be no remains of a neurotic predisposition as the child enters into manhood. The physical culture of such children should be carefully conducted; where a moderate amount of exercise builds up, too much exercise breaks down. The age and physical condition of each child must be taken into consideration, and such exercises, preferably outdoor, should be followed as circumstances permit. Whatever those exercises may be, the proper point is their continuance with regularity for years. Practical experience has shown that by the methods suggested children of undoubted neuropathic tendencies may, without the shadow of a doubt, develop into perfectly healthy men and women.

American Medicine, August 30, 1902.

Immunity and Articular Rheumatism.—Edmond R. Moras says that although there is an almost universal opinion that rheumatic fever, instead of conferring immunity, actually increases the disposition to the disease, his personal experience has been that one attack of acute articular rheumatism confers local immunity against another, whether the so-called individual disposition be increased or not. The writer asserts that acute articular rheumatism of any given joint or joints confers protection to such joint or joints against another attack in the same sense or degree that typhoid fever "protects" Peyer's patches against a second invasion, and that therefore there would seem to be no plausible reason for rejecting the assumption that, in a case of rheumatic fever, in which every joint had been typically affected, and complete recovery had ensued, the patient would be strictly immune as regards future attacks. Several cases are cited in proof of the author's claim, and he concludes his paper by stating that of still greater value is the negative evidence secured from every patient who happened to have articular rheumatism more than once. In no instance could he find that acute, subacute, or chronic articular rheumatism, when once fully recovered from, ever attacked the same joint or joints again.

The Effect of Rest upon the Progress of Septic Infections.—A. J. Ochsner says that although it is generally theoretically admitted that absolute rest is a most important part of the treatment of septic infections, he has observed that in practice this condition of rest is but rarely secured, and but seldom systematically striven for, except in the treatment of inflamed joints. He reviews the history of fifty-two cases of infection of the hand, treated in hospital, and extending over three years. In all these fifty-two cases there was not a single death, although many of the patients were brought to the hospital in a very septic condition, with high temperature and pulse, and frequently delirious. All those who came under treatment before incisions had been made recovered without deformity or stiffness of the fingers The treatment consisted in obtaining as nearly as possible perfect rest for the extremity, by placing the patient in bed, applying a large dressing, composed of sterile gauze and absorbent cotton, saturated with a mild antiseptic solution, the solution employed most commonly being hot saturated solution of boric acid, to which one-third, by volume, of strong commercial alcohol had been added. The whole dressing was covered with oiled silk or rubber cloth. Even in cases in which only the end of a finger was involved the entire arm to the shoulder was included in the dressing, making motion of the extremity almost impossible. The author says that although the hot, moist antiseptic dressings are probably beneficial in themselves, he is positive that the enforced rest is of equal value. In proof of this he observed frequently that an examination accompanied with much manipulation would invariably result in an increase in the affection, and that unnecessary movements during the changing of dressings would result in the same increase in the septic conditions. What is true in the case of infection of a finger tip is also true of infection of any other part, and the same principle obtains in acute peritonitis resulting from infection from the vermiform appendix, the fallopian tube, the gall-bladder, or an ulcer of the stomach. During the war in South Africa the surgeons found that, in penetrating wounds of the abdomen, if the patient was wounded while hungry and no food was given by mouth, quite a large proportion recovered, while of those in whom the alimentary canal was not kept absolutely at rest none recovered. The writer concludes his paper by saying that many other instances of this principle can be mentioned, such as the result of strapping in the treatment of mastitis during the beginning of the attack, the use of the splint or plaster-of-paris casts in inflamed joints, strapping of the chest with rubber adhesive straps in pleurisy, or bandaging the eyes in conjunctivitis. In short, that absolute rest should be the cornerstone in the treatment of all forms of inflammatory conditions in any part of the body.

Chronic Carbon Monoxide Poisoning and Carbonyl Hæmoglobinuria.—Thomas J. Yarrow reiterates his statement, first made two years ago, that chronic carbon monoxide poisoning occurs more frequently than is imagined, and is responsible for many obscure conditions which often remain an unsolved puzzle in the practice of every physician. He says that the large increase in the use of gas for cooking purposes will add to the evil, and that physicians should be prepared to make a diagnosis of this toxic condition as readily as they do of the acute form. He alludes to the fact that people engaged in placing gas-fittings in houses soon lose their sense of smell as regards the odor of gas, unless it escapes in large amounts, and says that in the same way people living in the house with a constant small leakage soon grow accustomed to its presence and cease to notice it. Carbon monoxide, as is well known, forms a very stable chemical combination with hæmoglobin, so that blood once impregnated with this deadly gas loses its power as an oxygen-carrier to the tissues of the body. The compound which is formed is of a bright florid crimson or purplish-red color, totally unlike normal blood, which is more of a yellowish-red hue. Individuals acutely poisoned with carbon monoxide show this peculiar color in their complexion It is the strong affinity that carbon monoxide possesses for hæmoglobin that renders recovery almost impossible in cases of severe poisoning by it. In the chronic cases the carbon monoxide coexists in the blood with oxygen, so that the hæmoglobin still retains a crippled function of carrying oxygen to the tissues. When an individual is exposed to a small but constant quantity of this gas, as from a leaky gaspipe or drain, the effect upon his health is soon apparent. The symptoms, though vague and misleading, may be summed up as follows: Anæmia, frontal headache (worse in the morning on arising), anorexia, tinnitus aurium, vertigo, foul taste in the mouth (sometimes expressed as "gassy"), abdominal pains, very often colicky in character, constipation, and persistent disorder of digestion. The patient is weak, he "never feels well," although much improved when in the fresh air, which fact should excite suspicion as to the cause of his illness. The chronic form differs markedly from the acute, as in the former type the florid countenance is seldom or never seen. The author believes it may be accepted as a fact that the chief injurious effect of the inhalation of illuminating gas is due to the carbon monoxide, the other constituents playing but a subsidiary rôle. Methane or marsh-gas, the firedamp of the mines, is not considered poisonous when mixed with air, and carbon dioxide probably plays but little part, as it is nearly all removed in the purification. After a report of two cases, the writer concludes by saying that chronic poisoning by illuminating gas should never take place, if proper precautions are taken to see that the fixtures are impermeable to gas, and if the valves are turned off completely.

Philadelphia Medical Journal, August 30, 1902.

Amyotrophic Lateral Sclerosis; Report of a Case.—E. J. French reports the case of a farmer, sixty-one years of age, whose symptoms were typical of amyotrophic sclerosis. The disease ran a comparatively rapid course, ending fatally fifteen months after the first symptoms were noticed. It is not improbable that chronic alcoholism was a causative factor.

The Positive Diagnosis of Meningitis, Particularly Tuberculous, by Means of Lumbar Puncture.—Alfred Hand, Jr., emphasizes the value of lumbar puncture as a diagnostic means in meningitis. The changes which occur in the cerebrospinal fluid as a result of this disease are diminution or absence of sugar, increase of albumin and, except in simple serous meningitis, the presence of leucocytes, bacteria, and frequently endothelial cells. When meningitis is suspected, lumbar puncture will definitely determine whether or not it exists and, if the proper technique is observed, it will enable us to tell in the vast majority of cases whether the process is tuberculous or not.

The Treatment of Pulmonary Tuberculosis.—William A. Caldwell says that it is well, before beginning treatment, to remember (1) That tuberculosis is a preventable disease—by destruction of the excretions known to contain the bacilli, and by keeping the organs and tissues of the body at their highest physiological function; (2) That it is a curable disease, as is shown by the reports of many sanatoria in every part of the world and by post-mortem statistics; (3) That there is no specific climate, although some climates have greater healing influences, and that it may be successfully treated in all climates; (4) That there is no specific medicine, only medicine which favorably influences the disease; (5) That to obtain the best results, an early diagnosis is necessary. We should not depreciate the great value of a sputum examination, but aim to make its positive findings confirmatory rather than diagnostic. He discusses the prophylaxis, the hygienic and dietetic management, and the treatment, symptomatic and general, by drugs. The principles of the hygienic-dietetic treatment are: (1) The patient lives continuously in the open air; (2) His nutrition is maintained by all available means, at the highest point; (3) Rest, suitable to the patient's condition and the stage of the disease; (4) All means consistent with the patient's condition are used to harden the tissues and render them impervious to the influence of the tubercle bacillus.

The Lancet, August 23, 1902.

A Case of Post-Operative Hæmatemesis.—Arthur H. Buck reports the case of an elderly spinster who was operated on for a complicated pelvic disorder. Thirty-six hours after the operation the patient vomited a large quantity of altered blood and a second similar quantity four hours later; the temperature fell to subnormal, but the pulse was not affected. The vomiting continued another day, but was finally controlled by repeated doses of liquor chloride of adrenalin and of calomel.

Reflex Movement of the Auricle of the Ear.—E. Donaldson observed, on insufflating into the meatus of a patient, some powdered boric acid through an ear speculum without holding the auricle, that at each puff the auricle moved distinctly forward to the extent of about one-eighth of an inch. He found that he also could produce this reflex movement by blowing air from a small india-rubber bag into the auricle in the neighborhood of the external meatus. He was careful to exclude voluntary movement, and movement that was only part of a more general scalp movement.

An Unusual Fracture of the Superior Maxilla.—Franklin Cox had occasion to treat a case in which the left superior maxilla was found to be fractured—the line of cleavage running along the roof of the mouth in the line of the intermaxillary suture, the two middle incisor teeth being almost out, and the mucous membrane being torn for one and a quarter inches in the line of fracture. Upward it ran obliquely to a point about a quarter of an inch above and external to the left ala of the nose, and then descended in a downward and outward direction to a point between the second upper bicuspid and the left first upper molar. The skin over the fracture was not lacerated so much as one would have thought probable, but there was a deep wound, laying the bone bare, and extending from the middle line of the upper lip about a quarter of an inch below the nose upward and outward to the left for about one and a half inches.

Heart Disease in Children.—A. E. Sansom considers what he calls the chief condition of heart disease in children, the rheumatic heart of childhood. Under this heading he includes (1) the temporarily swollen or enlarged heart of rheumatism; (2) the heart of rheumatic pericarditis; (3) the heart of rheumatic endocarditis with resulting valvular disease, severe or extensive; and (4) the heart of slow, insidious endocarditis, inducing mitral stenosis. In childhood the heart phenomena—not complications—of rheumatism are very much to the fore; there may be pericarditis, endocarditis, or the swollen heart of rheumatism, without any signs to show that there are arthritic phenomena present. Arthritis should not, therefore, be taken as an index of rheumatism which is not essentially, but only adventitiously, a joint process.

Three Cases of Banti's Disease.—James Barr gives abstracts of three cases that he has observed in males, aged respectively forty-eight, forty-two, and thirty-eight years. Each one met with a more or less serious accident to his abdomen some years before the occurrence of the present disease. The blood-pressure was low in all the cases, this no doubt being due to vasomotor paresis of the splanchnic area; the abdominal viscera were engorged, while the vessels of the rest of the body were comparatively empty. In all the cases there was a low form of chronic peritonitis with marked friction fremitus, but without any febrile temperature. In two of them there were ascitic and pleural effusions, but the complete disappearance of the fluid in one of them after a couple of tappings showed that the ascites was not due to the cirrhosis, and in the other case at the operations the liver was found to be fairly normal. In the third case the albuminuria indicated renal engorgement, and the well-marked erythromelalgia of both feet showed further vasomotor paresis. In all cases there was marked oligochromæmia. The author holds the view that Banti's disease is probably due to a vasomotor paresis of the splanchnic area, either in whole or in part, and that this paresis arises from disease of the visceral sympathetic ganglia. As a consequence, there is great engorgement of the abdominal viscera, especially of the spleen and liver, increased hæmolysis, with consequent oligochromæmia and oligocythæmia. The increased blood-supply to those organs eventually leads to fibrosis and lessened function.

Deutsche medicinische Wochenschrift, August 7, 1902.

Scalding or Burning of the Ear.—Treitel reports two cases, and shows wherein the symptoms are different from those which accompany traumatic injuries of this organ. The chief differences are, first, that in scalds or burns the destruction of the drum and congestion of the surrounding mucous membrane are much more extensive than in traumatism. This extensive destruction is brought about by a necrosis due to the heat. It is especially characterized by the small amount of pain to which it gives rise, and its speedy regeneration, so that, as a rule, within three or four weeks after the accident the repair is complete. The second peculiarity of this form of injury is the marked loss of hearing which accompanies it. This is much more marked than in traumatism. In those cases in which the destruction of tissue is not too extensive the return of hearing is usually complete.

Bovine and Human Tuberculosis.—Max Wolff records three series of observations in contradiction to Koch's views regarding bovine and human tuberculosis. The first series were made upon a case of primary intestinal tuberculosis which occurred in a man sixty-three years of age and which was fatal. The lungs and bronchial glands were never involved, but the mucous membrane of the small intestine, the peritoneum, the spleen, and the mesenteric glands showed many tuberculous lesions. Two guinea-pigs were inoculated subcutaneously with portions of the tuberculous spleen. Both of these animals were killed within seven or eight weeks following the inoculation, and showed the presence of numerous tuberculous lesions. A perfectly healthy five months' old bull calf was then subcutaneously inoculated with portions of the tuberculous organs of these guinea-pigs. This calf previous to inoculation had failed upon several tests to give the tuberculin reaction. One month after inoculation the calf gave a fairly well-marked tuberculin reaction, and three months thereafter this reaction was very marked. This calf was then killed and at autopsy the characteristic local and general lesions of bovine tuberculosis were found. This series of observations conclusively proves that the original tuberculous lesions present in the patient were produced by bacilli which were capable of producing lesions of bovine tuberculosis in the calf, and show without doubt that man is susceptible to bovine tuberculosis. The second series of experiments relates to the frequency of tuberculous infection through the intestinal tract without the development of local lesions therein. In these observations guinea-pigs were used and were fed with both human and bovine tuberculous bacilli. Many of these animals subsequently developed tuberculous lesions in their various organs without ever showing any tuberculous intestinal lesions whatsoever. In view of these results, it is certain that the widespread opinion which holds that intestinal tuberculous infection must be accompanied by intestinal lesions is entirely erroneous, and that consequently the chief premises upon which Koch founds his views are deceiving. The third series of observations relates the susceptibility of calves to infection with human tuberculous bacilli. For this purpose a healthy calf was taken which gave no tuberculin reaction. This calf was inoculated with a mixture of sputa obtained from several phthisical patients. At the site of inoculation an abscess developed, the pus of which contained many tubercle bacilli. Forty-eight days after inoculation the animal gave a marked tuberculin reaction. Five weeks later, however, this reaction had entirely disappeared. The animal was then killed, when it was found that none of its internal organs was tuberculous, but that at the site of inoculation typical tuberculous lesions were present. This experiment shows that calves are not entirely refractory to human tubercle bacilli, as claimed by Koch. These experiments taken in toto absolutely disprove Koch's views with respect to bovine and human tuberculosis.

Berliner klinische Wochenschrift, August 11, 1902.

A Review of Carcinoma from a Pathologico-anatomical Standpoint.—W. Riechelmann says that the increase in the frequency of carcinoma is to be ascribed to three causes: (1) The increased number of persons who live to the age at which this disease is most frequent; (2) Improved methods of clinical diagnosis; (3) The more abundant employment of anatomical methods of diagnosis. In view of these facts, it is questionable whether the increase in the frequency of this disease, which has recently been so widely proclaimed, is not apparent rather than real. The cachexia in carcinoma is due to three factors: (1) Reduction in the consumption or assimilation of food; (2) Ulceration and sloughing of the tumor; (3) Number and location of metastases.

Agglutination of the Pest Bacillus.—Aladar Anjeszky and Johann Wenhardt, as the result of experimental research, announce the following conclusions: (1) The pest bacillus is agglutinated by normal horse serum, but not in dilutions above 1 to 10. (2) Pest serum in dilutions below 1 to 5 agglutinates not only the pest bacillus but also other bacteria. (3) The blood of normal individuals and those suffering from tuberculosis if in a feverish condition does not agglutinate the pest bacillus. (4) Normal rabbit serum does not agglutinate the pest bacillus, but such an agglutination is quickly produced by the serum of rabbits which have been immunized with pest serum. (5) The urine of normal individuals does not agglutinate the pest bacillus, but the urine of such persons who have been inoculated with pest serum does so agglutinate. (6) The serum of rabbits which have been inoculated with Haffkine's fluid does not agglutinate the pest bacillus. (7) Haffkine's fluid is suitable for agglutination tests, but the reaction is not so pronounced as when living pest bacilli are employed.

Münchener medicinische Wochenschrift, August 12, 1902.

Operative Treatment of "Plastic Induration" of the Corpora Cavernosa Penis.—E. Galewsky and W. Hubener report the first case of "plastic induration" of the corpora cavernosa penis which has been operated upon with permanently good results.. The patient was forty-seven years of age and gave a history of syphilis of twenty-three years' standing. The "induration" had been present for about six months, during which time it had increased in extent so that coitus had become impossible. The "induration" was evidently of traumatic origin. It has been unsuccessfully treated, both locally and internally, by the means of various iodine and mercurial preparations. Upon operation the indurated tissue was removed and the wound closed with catgut sutures. Primary union took place. It is now two and one half years since the operation was performed and no recurrence has taken place. A microscopical examination of the tissue removed showed that it was composed of colloid like fibromatous tissue containing very few connective-tissue cells and sparingly supplied with blood vessels

Disappearance of the Patellar Reflex in Pneumonia.—Hugo Luthye refers to Pfaundler's recent article upon this subject and says that, in his own experience, such reflexes have been absent not only in children, but also in persons of all ages. This absence may be uni- or bilateral. As a rule a total absence of the knee phenomenon is shortly followed by a marked reduction in the vitality of the patient Since an absence of the patellar reflexes is frequently encountered in any of the various infectious diseases, its value in the diagnosis of pneumonia is very doubtful, notwithstanding Pfaundler's opinion.

Etiological Relations between Chorea Minor and the Infectious Diseases, Especially Rheumatism. George Koster reviews the literature and gives the statistics relative to 121 cases of chorea which came under his observation. Of these 121 cases in eighty-six there was a combination with some acute infectious conditions. In seventy instances this combination was with some manifestation of rheumatism. In sixty-three the rheumatic attack preceded the chorea, in three the two diseases appeared simultaneously, and in four the chorea was primary. These figures show conclusively that a close relation exists between these diseases. The exact pathological foundation of this relation is not clear at the present time, notwithstanding the various theories which have been advanced with respect thereto. Many unsuccessful attempts have been made to cultivate from the blood of choreic patients microorganisms which are regarded as causative of rheumatism (streptococci, staphylococci, etc.) Until this shall have been successfully accomplished the direct infectious nature of this relation cannot be regarded as demonstrated.

Production of Hæmolytic Amboceptors by Serum Inoculation.—Paul Theodor Müller reports a new series of experiments along this line. This author has previously shown that a number of normal sera possess anti-hæmolytic properties under certain conditions. Thus normal guinea pig's serum possesses such an anti-hæmolytic property when added to a mixture of guinea-pig and rabbit blood; but this is only shown when such normal guinea pig's serum has been previously heated to 55°–60° C., or, in other words, made inactive. The author believes that this is due to the fact that the non-heated serum contains anti-hæmolytic substances which are united to thermo-labile components, and thus rendered inactive until these components are destroyed by heat. If this reasoning is sound it should be possible to produce by animal inoculation with the inactivated serum anti-bodies which should nullify the action of the same while the inoculation of the active serum should not give rise to such anti-bodies. By a series of inoculations the author shows that in reality this is the case and that the inactivated guinea-pig's serum possessed anti-hæmolytic properties because it contained receptors which are similar to those present in guinea-pig erythrocytes, and upon suitable animal inoculation for the same reason it gives rise to amboceptors which are active against such guinea-pig erythrocytes. The amboceptors therefore, which are produced by the suitable inoculation of inactivated guinea-pig serum, are hæmolytic for the erythrocytes of the guinea-pig, and will prevent the anti-hæmolytic action of the inactivated guinea-pig serum.

French and Italian Journals.

The Resection of Arteries.—Edoardo Salvia carried out a series of experiments on dogs, donkeys, and sheep, resecting their arteries, and removing the portion operated on for purposes of examination from five to thirty-five days later. One fact ascertained was that the lesions vary greatly according to their situation. Another interesting point was that absorption of the silk sutures occurred through the agency of giant cells. The behavior of the leucocytes varied greatly in the different cases. Operations on small animals were less satisfactory than in large ones, because of the difficulty in keeping the canal of the smaller vessels pervious. In the large animals, the operation was perfectly successful, all the tissues—with the exception of the elastic fibers—having shown complete restoration.—*Giornale Internazionale delle Scienze Mediche*, July 31, 1902.

Inguino-Crural Herniæ of the Cæcum, with Incomplete Sac. Léon Bérard and Paul Vignard, in discussing this subject, state that the prognosis of herniæ of the cæcum in general, and more particularly of the herniæ with an incomplete sac, ought always to be guarded, even without consideration of the periods of strangulation. These herniæ are most often observed in adult subjects, more or less obese, or having relaxed abdominal walls, so that a large hernial mass is always liable to pass through the rings. These patients are very apt to be affected with some bronchial trouble. Generally herniæ of the large intestine are difficult to operate upon. There is danger of opening the cæcum, which is mistaken for the sac. Adhesions also add to the difficulties of operation. It is a most interesting and delicate problem to restore the adherent loop without compromising its vitality.—*Gazette des Hôpitaux*, August 2, 1902.

Obstetrical Intoxication of a New-born Child.—Fieux reports the case of a young primipara who at term had a prolonged labor. There was premature discharge of the waters, and Champetier's bag was employed. After sixty-three hours of labor a living infant was extracted by means of forceps. At no time during the labor had the fœtus expelled meconium. The heart beat was not weakened. Eighteen hours after birth the infant cried without ceasing; it was very restless. There developed on the back a large patch of erythema. It had not swallowed anything, and there was no umbilical infection. Hot enemata were given and purgatives were administered, which caused the discharge of fetid fæces. Recovery was rapid. The disorder was evidently an infection of intestinal origin. This had started *in utero* and was favored by the length of the labor.—*Journal de Médecine de Bordeaux*. August 3, 1902.

Myeloid Osteosarcoma of the Inferior Extremity of the Radius.—Jaboulay describes the case of a man, the lower third of whose right radius had been destroyed by a myeloid sarcoma. The arm had been treated by incision and curettage of the neoplastic masses. The hand was unstable after this operation, and in order to give it support, the wound was well tamponed with sterilized gauze. These tampons were left in place for six months. Solid bony growths had sprung up all around the tampons. The writer concludes that in cases of myeloid sarcomata of the ends of the long bones of the extremities, it is not wise to amputate nor even to resect, but simply to incise and to fill up the neoplastic cavity with tampons of sterilized gauze. These will give rise to an irritation which will end in the growth of bone, and this will reunite the ends of the diseased bone.—*Lyon Médical*, August 3, 1902.

Fibroma of the Abdominal Wall.—Caubet reports a case of fibroma of the abdominal wall, which developed in a woman of thirty years during the course of her third pregnancy The tumor was ovoid, and as large as a hen's egg. The anterior surface was very adherent to the small oblique muscle, while its posterior surface lay against the subperitoneal fat without any adhesions. The tumor appeared to develop at the expense of the transversalis muscle and its aponeurosis. Each pole of the tumor had a pedicle. The internal pedicle was slender and about 12 cm. long. It passed in front of the bladder and was inserted on the posterior surface of the pubis. The other pedicle was short and thick and was attached to the iliac crest. The two pedicles were fibrous and not vascular. They appeared to be prolongations of the connective tissue capsule which enveloped the tumor, and not an outgrowth of the tumor itself. The histological structure of the tumor was that of a pure fibroma.—*La Presse Médicale*, August 2, 1902.

Generalized Osteosarcomatosis.—Griewank reports a case of this kind. The patient was forty-eight years old. The family history was negative: the patient had suffered from pleurisy nine years before. The present trouble had begun nine and one-half months before he entered the hospital, when one day, on making a slight effort, he felt a sharp pain in the region of the right tenth rib. In a few days he took up his work again. But some days later he had the same pain on the opposite side in about the same place. Still later, he suffered great pain in his left leg along the course of the sciatic nerve. He had great difficulty in walking. He was treated for sciatica and gradually improved. Then there appeared on his head and lower jaw indolent tumors, which continued to grow. He then suffered pain at the internal extremity of the left clavicle. The tumors on his head gave a parchment-like sensation. Finally, owing to a slight effort made by the patient, the humerus was fractured. This was undoubtedly spontaneous and is easily explained by the state of malnutrition of his osseous system.—*Journal de Médecine de Bordeaux*, August 3, 1902.

A Rare Form of Arterial Lesion.—Antonio Cesaris-Demel describes a case in which the primary lesion occurred in the elastic fibers of the vascular walls of the large and the medium-sized arterial trunks. In the abdominal aorta and in its principal branches there was a secondary lesion consisting of a solution of continuity in all three of the vascular layers, with interstitial and extravascular infiltration of blood. There was no degeneration, whether fatty, amyloid, or hyaline of the vascular walls. A study of the case led the author to exclude from the etiology any mechanical, septic, or toxic influence, or any disturbance of embryonal origin. The primary lesion appeared to be a special form of degeneration due to a disturbance in the trophic centers, as shown by the passivity of the purely destructive process, which was unaccompanied by the slightest sign of inflammatory reaction. It effected the elastic fibers only of the arterial walls, and did not extend to any other elastic tissue in the body. This case sustains the theory advanced by Reklinghausen and others, that aneurysms may be due to primary and isolated rupture of the elastic fibers of the vascular walls, independently of any previously existing inflammatory or degenerative changes.—*Archivio per le Scienze Mediche*, No. 3, 1902.

Melanotic Tumor of the Skin.—Vittorio Valle reports the case of a man of twenty-one years who had a superficial tumor situated on the anterior aspect of the thorax which measured about 10 cm., horizontally, and 6 cm., vertically. It was not smooth, but blackberry like in shape, of a slaty gray and shining color. A second, smaller tumor was situated just above it, and an enlarged gland, the size of a walnut, surrounded by smaller swellings, could be felt in the axilla. The patient refused operation, but a small portion of the growth was excised and examined microscopically. The conclusions reached from the examination were: (1) The confirmation of the fact that a melanotic tumor of rapid development may originate from a pigmented mole, mechanical or chemical irritation (in this case, treatment by silver nitrate) may bring about this result; (2) The neoplastic melanotic cells are probably found by the transformation of cells that were originally indifferent, while the adult cells disintegrate; (3) In this tumor the pigment took its origin in the middle of the cell in the form of granules, and in the adult cells it was found dissolved in the plasmatic fluid. The author is unable to decide whether the case is one of melanotic sarcoma or of epithelioma.—*Annali di Medicina Navale*, June, 1902.

The Rational Treatment of Diabetes.—A. Lorand first discusses what result is to be looked for in the treatment of diabetes. He gives as his opinion that diabetes is a malady which can never be radically cured. The sugar may be caused to disappear from the urine, but after having obtained this result, we have only caused the disappearance of one symptom of the disease. The constitutional vice, the morbid condition ,still persists in other forms. On this basis, every strong emotion, every indiscretion in diet, will resuscitate anew the diabetic syndrome. He speaks of patients from whose urine every trace of sugar had disappeared for a time only to reappear again. The object of treatment then of these patients should be to procure for them as long a period as possible in which they do not eliminate sugar and to keep them in as comfortable physical condition as possible. He considers hydrotheraphy as the most valuable therapeutic measure—the use of mineral waters. Diet, muscular exercise, baths, rest from all work, and certain drugs are also recognized. But the most valuable treatment is the preventive treatment. It is of more value to discover a case of beginning diabetes than it is to diagnose a great number of cases of grave diabetes. For to the first patient you can promise a long life, while for the second you can only prolong for some years a life full of suffering. —*Annales de la Société Royale des Sciences Médicales et Naturelles de Bruxelles*, 1902.

Double Wound of the Heart by a Ball; Suture, Cure.—In the service of Launay was a young man of twenty-six years, who was wounded by a revolver in the region of the heart. Three hours afterward percussion revealed a great abnormality in the entire left half of the thorax. On this side the respiratory sounds were not perceptible, and the heart beat was feeble and muffled. From time to time, clapotage could be heard. A penetrating wound of the left pleura and of the heart was diagnosed. Operation was at once performed, and a large opening made in the left thorax. The pleural cavity was filled with air and blood. This came from a pericardial wound near the apex of the heart. The pericardium was incised and the heart was beating violently, and there was a wound in the anterior surface of the left ventricle, from the orifice of which the blood poured out at every diastole. This was easily sutured with catgut. The orifice of exit of the ball in the posterior surface of the left ventricle near its base was also sutured. The pericardium was then cleansed of clots and a drain was placed in the lower part. The pleura was cleansed and a drain was inserted here. The two drains were attached to the wall and the wound sewed up. At the end of forty-eight hours the drains were withdrawn; the stitches were taken out on the eighth day. In a short time the patient had entirely recovered. This is a most unusual case, the serious wound being followed by recovery.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, August 3, 1902.

Sarcoma of the Kidney.—This case was in the service of Poncet, and was reported by Romme. The patient was a man of twenty-six years with a negative family history, with the exception of an aunt who died some years ago with cancer of the breast. The first illness that the patient had ever suffered from was two years ago, when the lower part of the femur was amputated for an osteosarcoma. He was supposed to be entirely cured, and his health remained good until a year ago He then began to suffer in his left lumbar region. Three months ago a tumor appeared in the left side, which was tender on pressure. A median laparotomy was performed, and the patient was informed later that the tumor was inoperable. He sought other advice and entered the Hôtel-Dieu. He complained of pain in the abdomen and in the loins, especially on the left side. This pain was not very severe. There was a large tumor in the left renal region. It was hard and slightly movable with respiration; but it was easy to obtain renal ballottement. Aside from the pain, there were no functional symptoms in particular. There was no hæmaturia, and the urine was not abnormal. Finally, there developed on the left side a varicocele, which was very marked. The general health began to decline, but there were no signs of generalization. The liver seemed to be normal and the patient did not cough. Sarcoma of the kidney was diagnosed, and the tumor was removed, and the diagnosis was proved to be correct. The case is interesting on account of recurrence taking place in the kidney, and on account of the absence of urinary symptoms.—*Lyon Médicol*, August 3, 1902.

Book Reviews.

THE MEDICAL STUDENT'S MANUAL OF CHEMISTRY, Fifth Edition. By R. A. WITTHAUS, A.M., M.D New York: Wm. Wood & Co., 1902.

THE present edition of Dr. Witthaus' book presents a number of modifications from the preceding works in the following particulars: The sections devoted to organic and inorganic chemistry have been condensed; that devoted to laboratory technique has been omitted, while a separate section has been added dealing with the important subject of physiological chemistry. Though the book is termed a medical student's manual, there are many chapters in which some of the matter is hardly within the grasp of the average medical student. This is applicable more particularly to the sections on organic and inorganic chemistry, which is dealt with in considerable detail and in contrast to the simplicity of the chapter on physics. This, however, in no wise detracts from the value of the book as a medical student's manual, since the too advanced sections may be omitted, and it raises it to the level of a sufficient textbook for the student of chemistry.

In this edition the author has supplied for the practitioner a ready reference to concise information concerning the alkaloids, albumins, ptomains, etc, together with the details of numerous laboratory methods for the detection of normal and abnormal ingredients of the body fluids in an exhaustive and lucid manner, and has quite kept the subject up to the spirit of modern medical thought.

Books Received.

While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

APPLIED SURGICAL ANATOMY. By GEORGE WOOLSEY, M.D., 8vo. 521 pages. Illustrated. Philadelphia: Lea Brothers & Co. Price, cloth, $5. net; leather, $6 net.

THE DISEASES OF THE NOSE, THROAT, AND EAR. By CHARLES PREVOST GRAYSON, M.D., 8vo. 540 pages Illustrated. Lea Brothers & Co. Price, cloth, $3.50 net.

The Digestion of Bacteria. Turro, by exposing cultures of anthrax bacilli to various animal products, arrives at certain conclusions as to the digestive power of the latter on microorganisms. The organs were taken from the ox or hog on the day of slaughter, were finely minced, and the juice was expressed. It was found that the juice so obtained from the thyroid, kidney, and muscle completely digested at least 10 per cent. of its weight of a one-day culture of anthrax bacilli in from one to three days, a temperature of from 35 to 38° C being maintained. By the addition of 2 per cent. of sodium fluoride the digestive process was not impeded, but the absence of contamination by other bacteria was assured. A mixture of the white and yolk of egg possessed digestive powers that increased with time. The first indication of the chemical change in the anthrax bacillus was its loss of affinity for the basic dye of Gram's method, while the less advanced was the digestive process the more deeply it stained with eosin. The end product of the bacteriolysis was a slimy material of gray color. From a chemical standpoint bacteriolysis seems to be a hydrolytic process, the enzymes in question attacking the organism either by erosion from without or by imbiition according to their degree of solubility and diffusibility. Freshly-cultivated organisms were found by Turro to be less resistant to the zymotic action than those that had stood for a certain length of time or had been treated with mineral acids or by heating.—*Centralblatt fur Bakteriologie.*

Hemorrhage into the Spinal Cord During Pregnancy.—Alexander Bruce gives the following resumé of the principal symptoms in the case. Onset at fifth month of pregnancy, during an act of vomiting, of sudden pain in the back and trunk, with paralysis of the lower limbs and trunk muscles, paralytic retention of urine, constipation and great dypnœa; sensation absolutely lost below xiphosternum; paralysis flaccid during rest of life; loss of left, persistence of right knee-jerk; extensor response to tickling sole; disappearance of deep reflexes after six days, and slight reappearance of them ten days later; slight temporary weakness of both hands; rapid formation of bed sores; painless and unconscious birth of twins at seventh month; death from bronchitis and exhaustion At autopsy hemorrhages into the spinal cord were found, due to small tumors already existing in the cord, but giving rise to no symptoms. The occurrence of parturition in cases of anæsthesia and paraplegia are extremely rare. Amand Routh has collected six, and concludes that if the lesion is in the lumbar region the uterus may begin the labor automatically, but cannot complete it; if above the lumbar region, the act can be completed, showing that the reflex mechanism in the lumbo-sacral region is sufficient of itself without any voluntary assistance. The case reported supports the latter conclusion, and also shows that the sensory path from the uterus enters the cord in the lumbo-sacral (or possibly lower dorsal) region.—*The Scottish Medical and Surgical Journal.*

The Use and Abuse of Tobacco.—Robert E. Coughlin concludes from his researches that in convalescents we should prohibit the use of tobacco until strength is fully restored. In all functional heart cases, in impotence and sexual decline, look into the patient's tobacco history. In some persons tobacco has no bad effects, even when consumed in large amounts. When it gives an agreeable feeling of comfort it does no harm, but possibly good. It should not be used by the growing youth nor by women, on account of their susceptible nervous symptoms. In their order of harmfulness the different ways of using tobacco may be set down as follows: snuff-taking, chewing, cigar smoking, pipe smoking, and cigarettes. The trouble with cigarettes is that smokers are apt to inhale, and are constantly lighting a fresh cigarette, sometimes using as many as fifty in one day.—*New England Medical Monthly.*

SECTION OF SURGERY

MR. JAMES HARDIE, PRESIDENT, IN THE CHAIR.

Wednesday, July 30—First Day.

A Discussion on Inoperable Cancer.—Mr. HENRY MORRIS of London opened this discussion. Cancer was defined as malignant disease in the widest sense, and the term inoperable as applicable to all cases beyond the reach of the knife. The local origin of cancer was now universally accepted. So long as we were ignorant of the true cause of cancer so long would all methods of treating inoperable cancer be essentially empirical and the reported cures be incapable of explanation.

The various methods of treating inoperable cancer were considered seriatum

Serumtherapy by means of Coley's fluid, at present only curative in a limited proportion of cases of spindle-celled sarcoma, had probably a more extended range in the future when other toxins or blends of toxins might be discovered applicable to various types of malignant disease.

The injection of cancroin, of cholesterin, and of various forms of soap, and the process of freezing had not been found satisfactory. Dr. Beatson's treatment—double oöphorectomy and the administration of thyroid extract—was based on scientific induction. It was, however, not only restricted in its field of application, but uncertain in its results, so that it was doubtful if it would take a permanent place in the treatment of cancer. Mr. Morris did not approve of its being employed in early cases as an adjunct to operation since the influence of oöphorectomy was neither stable nor permanent, and it was better, therefore, kept in reserve in case of recurrence.

The physical methods of treating cancer by means of light, Röntgen rays, and high frequency currents were purely empirical, and were evolved from the good results obtained in the treatment of lapses. The comparative merits of the Finsen light and of the Röntgen rays were considered in relation to Rodent cancer. The reported cures of cancer of the jaw, breast and uterus by means of high frequency currents, were too recent to afford a basis for judgment as to the merits of this method of treatment.

In conclusion, it was contended that the boundary between cases of operable and inoperable cancer needs to be adjusted from time to time, that it was open to question whether certain operations now performed for cancer should not be given up or restricted, and finally that further investigations into the nature and causes of cancer were required in order that the treatment of the disease might be placed on a scientific basis.

Dr. BEATSON of Glasgow referred to the capriciousness of cancer and to the undoubted occurrence of spontaneous cure of the disease. While a firm believer that the best treatment of cancer was removal by means of the knife wherever possible, the results already obtained in combating inoperable forms of the disease were decidedly encouraging for the future. He had found phenacetin the best drug for the relief of pain, and he was a strong believer in the administration of small doses of thyroid whenever this agent could be borne. Concerning oöphorectomy, the best results had been obtained in patients over forty years of age, and the menopause was no contraindication to its employment. Its influence was quite uncertain and in the presence of visceral metastares it was of no value. He did not believe in the parasitic origin of cancer.

Mr. THOMAS BRYANT of London recorded his experience of the treatment of inoperable cancer by means of Röntgen rays and reported a number of cases in which remarkable improvement had taken place. The cases included examples of cancer of the rectum, uterus, and upper jaw. Great skill and care were required in carrying out the treatment.

Professor WILD of Manchester discussed the subject of inoperable cancer from the standpoint of the physician. He had seen nothing but harm result from the administration of thyroid, and he had seen no benefit from arsenic, even when given in enormous doses. Opium was the best drug for the relief of pain, and hyoscine was a valuable substitute to break or prevent the morphin habit.

Mr. BROOK of Swansea showed photographs of cases of mammary carcinoma in which remarkable improvement had followed the use of Röntgen rays. He also referred to cases of epithelioma of the lip of the rectum in which they were of no value.

Mr. PAUL BUSH of Bristol had never seen any permanent benefit from the use of the Röntgen rays.

The discussion was continued by Mr. F. B. Jessett, Dr. Bogot Ferguson, Dr. Drage, Dr. Herbert Snow, Dr. Manders and Dr. McFeely. The discussion occupied three hours, the entire time at the disposal of the section for the day.

Thursday, July 31.—Second Day.

MR. SOUTHAM, VICE-PRESIDENT IN THE CHAIR.

Treatment of Tuberculous Disease of the Testis, Vesiculæ Seminales, Prostate, and Bladder.—Sir THOMAS MYLES opened this discussion. The pathological relationships of tuberculous disease in these various organs were briefly reviewed. From the point of view of treatment, cases of *testicular tuberculosis*, the speaker said, might be classified into the following groups:

1. Cases in which there were one or two small nodules in the epididymis in individuals otherwise in perfect health. In these, partial operations were recommended, the disease being removed without regard to anatomical structure. In the event of failure to cure, the whole organ should be removed.

2. Cases in which isolated nodules were present along with disease in the seminal vesicles and prostate. Such cases while quite amenable to operation were rarely benefited to an extent which would make such operations justifiable.

3. Cases of extensive testiculous disease with sinuses, but without infection of the prostate or vesicles, were best treated by complete excision of the organ.

4. Similar cases, complicated by disease in the prostate and vesicles, should be left to nature, or the testis might be removed in the expectation that thereby the general health might benefit.

5. Cases in which both testicles were involved made the most severe call on the judgment of the surgeon. Each case was to be decided on its own merits, but the fact remained that in spite of its social and mental disadvantages, double castration, was sometimes indicated, in order to save a life which was valuable to others as well as to the owner.

6. Cases in which there existed tuberculous disease in the lung or elsewhere in the body were exempted from local operative interference. Regarding tuberculosis of the bladder, the speaker was opposed to surgical interventions except in so far as it might be required for the alleviation of symptoms. Primary tuberculous disease of the seminal vesicle was practically never met with. When associated with disease in other parts of the tract, the removal of the vesicles, although quite practicable, was very rarely indicated.

Professor SENN of Chicago adopted a conservative attitude toward the question of operation in genitourinary tuberculosis. The surgeon was apt to forget the curability of these lesions by means of general treatment. He was a strong believer in the use of iodoform.

Dr. FERD. C. VALENTINE of New York maintained that there was an association between gonorrhœal and tuberculous lesions of the genitourinary apparatus, but this view was not accepted by the other speakers.

Mr. Jordan Lloyd of Birmingham laid stress on the necessity of distinguishing between genital and urinary types of tuberculosis, and declared himself in favor of radical operative treatment, although he admitted the possibility of spontaneous cure.

Mr. Southam of Manchester had observed very satisfactory results from double castration even in cases in which the prostate and vesicles were also implicated.

Mr. Rutherford Morrison of Newcastle approved of removal of the testicle because it afforded rest to the diseased vesicle. He had never seen any good from iodoform in tuberculous lesions.

Two Cases of Chronic Pancreatitis Treated by Laparotomy.—Mr. Edmund Owen reported these cases. The chief point raised was whether the benefit from operation depends on opening and draining the gall-bladder when this is found to be distended.

Mr. Griffiths of Swansea had had a successful case in which he had drained the gall-bladder.

Sir Thomas Myles also had had a successful case in which he had opened and then closed the gall-bladder.

Mr. Balziel of Glasgow had had two successful cases; in one he had not drained the gall-bladder, while in the other he had removed a stone from the pancreatic duct,

Mr. Rushton Parker presented statistics of 300 operations for tuberculous glands performed during the last thirty years.

The Value of the Imperfectly-Descended Testicle.—Mr. McAdam Eccles read a paper of great interest on this subject. Most stress was laid on the advisability, when operating for the conditions and finding it impossible to bring the testicle down into the scrotum, of returning it into the abdomen, for although it would never form spermatozoa it would probably supply the so-called internal secretion.

Gallstone Operations.—Mr. Rutherford Morrison described the results of operation in forty-three cases of gallstones. He recommended the employment of an incision commencing in front at the junction of the upper and middle thirds of a line drawn from the ensiform to the umbilicus and extending to a point below the apex of the twelfth rib.

Friday, August 1.—Third Day.

Extirpation of the Prostate for Senile Enlargement.—In opening this discussion, Mr. Freyer described and eulogized his own method by the suprapubic route, and recorded the details of seven cases in addition to those already published, making in all twenty-one cases. One patient of the latest series had died on the ninth day. All the prostates removed were exhibited, and made an imposing show on the platform table. Regarding the debated question of the prostatic capsule, his idea was that the organ was composed of two separate prostates or lobes, each having its own distinct capsule intimately blended with the prostatic tissue, while outside there was a common fibrous sheath derived from the vesical fascia. The enucleation was effected between the capsule and the fibrous sheath.

Dr. Alexander of New York, with the aid of a series of enlarged photographs hung on the screen, gave a demonstration on certain points in the surgical anatomy of the enlarged prostate. He maintained that the enlargement which caused obstruction of the urethra chiefly proceeded from the lateral lobes, and that the best method of attacking it was by the perineal route. Having performed a median perineal section and opened the membranous urethra, the prostatic urethra is dilated with the finger. The mucous membrane over one or other lateral lobe is torn through with the finger nail which enters the line of cleavage between the capsule and the sheath and enucleates each lobe in succession from behind forward. There was the least possible damage to the urethra and surrounding structures, and the wound approaches the surgical ideal. There was no incontinence unless the sphincter at the neck of the bladder was destroyed.

Dr. Parker Syms of New York advocated the perineal route and recorded a series of twenty-one cases of extirpation without a death. He demonstrated an inflatable rubber retractor, which, when introduced into the bladder through the perineal wound and inflated, enabled me to pull down the prostate, making it more accessible and reducing the hemorrhage to a minimum.

Mr. Reginald Harrison exhibited his own specimens removed by operations and declared himself to be in favor of the perineal route. The damage to the deep urethra was an important objection to the suprapubic operations.

Sir William Macewen referred to the work of McGill of Leeds, recalling the pioneer work which that surgeon had done in developing the operation of suprapubic prostatectomy. Personally, he was inclined to favor the perineal route as being easier and comparatively bloodless, as entailing less risk of damage to the urethra, and as affording efficient drainage in septic cases.

Mr. Freyer, in reply, maintained that his own operation was the best, and complained that his work had not received that recognition which it deserved.

The discussion was followed with great interest by a very large audience, the impression gained was one of impartiality toward the two methods of extirpation.

Non-malignant Affections of the Stomach Treated by Gastroenterostomy.—Mr. Balziell of Glasgow reported a series of thirty cases of this nature. The posterior operation was performed in all but four cases, the anterior being performed in one case by selection and in the others of necessity, because of extensive adhesions preventing access to the posterior surface of the organ. Only one patient succumbed after the operation.

Transverse Incision of the Peritoneum in Median Laparotomies.—W. Poten describes a method of opening the peritoneal cavity, which he has found very advantageous in such an operation as hysterectomy for carcinoma when extensive dissection is necessary. The usual median incision is carried down to the peritoneum, and the edges of the wound are well retracted. The peritoneum is then stripped from the abdominal wall at the lower portion of the incision well out to either side, which is readily done, owing to the large amount of loose areolar tissue present in this situation. The entire anterior parietal peritoneum of the lower pelvis is thus exposed, and is now incised transversely just above its line of reflection from the bladder. An apron-like flap of peritoneum results, which when the intestines have been allowed to slip up out of the way in the elevated-pelvis position, is carried back to the posterior abdominal wall, and is sutured to the rear of the pelvis and across the rectum just below the sacral promontory. The intestines are now completely excluded from the field, and, if desired, the table may be let down and the rest of the operation be done extraperitoneally. After the necessary excision of the uterus and parametria has been performed the pelvic cavity is closed in by uniting the cut edges of the vesical and rectal peritoneum, while above this a space is left bounded below by this line of suture and above by the connective tissue side of the parietal peritoneum. The advantages of the method are that the peritoneal cavity remains shut off during the operation, thus diminishing the chances of infection, the intestines are not exposed to the air and the consequent cooling, nor to the mechanical insults of the use of abdominal pads, so that the risks of shock are greatly diminished, and there is less chance of the development of postoperative ileus, and finally, after the greater cavity has been shut off, the inconvenient elevated-pelvis position may, to a large extent, be dispensed with.—*Centralblatt fur Gynakologie*

Clinical Department.

A CASE OF PERITONITIS OF UNKNOWN ORIGIN.

By JOHN G. SHELDON, M. D,
TELLURIDE, COLO.

A WELL-DEVELOPED laborer, thirty-five years of age, was suddenly seized with a sharp pain in the abdomen. This happened about 4 P.M. while he was digging an irrigating ditch. The pain was of a colicky nature for five or six hours; then it became continuous and was located in the lower part of the abdomen. During the second night of his illness, the patient felt easier and slept some. On the third day his pain was worse and continued to increase in severity till I saw him—four days after the onset of his trouble. The patient had chilly feelings during the first few hours of his sickness, but he had had no definite chill. He vomited once —twelve hours after the onset of the pain—and had hiccoughs throughout the fourth day of his illness. His bowels were constipated but moved, on the third day, in response to a large dose of castor oil. Urination was normal. The patient stated that his entire abdomen was painful and tender and although his trouble at times seemed unilateral he believed that the right side had been more uncomfortable than the left.

Two years previously he was confined to his bed for ten days, suffering from pain and tenderness in the right side of the abdomen, accompanied by fever and some vomiting. Four years ago the patient had a similar—though less severe—illness. Other than these two attacks of sickness, he had always been well excepting a slight attack of rheumatism—ten years ago—and an occasional bad cold.

Examination, four days after the onset of the illness, was as follows: Cheeks and eyes sunken. Tongue diffusely and heavily coated. Pupils equal and react normally; no icterus. Temperature, 101° F; respiration, 22; not labored or jerky; expansion and excursion equal and normal. No friction fremitus felt. Voice fremitus normal. Auscultation showed the presence of coarse râles over the right lower lobe posteriorly, but otherwise the lungs seemed normal. The heart was not enlarged or displaced. No thrills or murmurs could be detected. The pulse was beating 120 per minute—small and hard but regular. The second sounds of the heart were not accentuated. The abdomen was slightly distended; was diffusely rigid and tender. No peristalsis could be felt or heard. The appendix region did not seem more tender than did the corresponding region on the left side. The right rectus muscle was not more tense than was the left. No movable dulness was found. The liver and spleen seemed normal, as did the genitals, extremities, lymphatics, and nervous system. Rectal examination was negative. The rectum was ballooned but the prostate seemed normal and no mass could be detected in the abdomen. Neither could the presence of ascites be determined even when the patient was in the sitting posture.

A diagnosis of peritonitis was made and—as I had never seen a case of primary peritonitis—I looked for the cause of the peritoneal involvement. Gall-bladder disease, gastro-intestinal ulceration, and disease of the genito-urinary system seemed improbable. The history of the two attacks of sickness led me to suspect the appendix as the starting point of the peritonitis in this case. Against appendicitis stood the fact that the appendix region had not been more painful or more tender than any other part of the abdomen. However I advised a laparotomy and expected to find the appendix the cause of the peritonitis.

On opening the abdomen, the small intestines and to a less extent the ascending colon and the parietal peritoneum were seen to be reddened, injected, œdematous and covered with a fibrinous exudate. A slight amount of sero-sanguinous fluid but no pus was present in the peritoneal cavity. The position of the appendix was less involved than that of the small intestines. The distal end of the appendix was curled upon itself and showed scar tissue and evidences of a previous but not a present inflammation. The ileum showed no evidences of involvement of Peyr's patches, that is. I could find no thickening or induration in the region corresponding to their location. The bladder was not enlarged, and no solid particles could be felt in it. No localized thickening or induration could be felt in the stomach walls. No areas of fat necrosis were seen; and no tumor was found in the region of the pancreas.

On two occasions during the operation some of the small intestines escaped from the wound. They immediately became distended and were replaced with difficulty. I removed the appendix, not knowing what else to do, filled the abdominal cavity with saline solution, and left a gauze and a rubber drain in the wound.

An enema consisting of castor oil and magnesium sulphate, each one ounce, with some glycerin and water, was given shortly after the operation. Two bowel movements were obtained about eight hours later. The patient gradually grew weaker. His pulse became more rapid and his temperature became higher. Twenty-four hours later he developed a cough and expectorated blood. The attending physician informed me that there were many râles over the lungs but that he was unable to find any consolidation.

The man died forty-eight hours after the operation. I was not present at the autopsy. The physician who made the examination informed me that he found the entire peritoneum involved in the inflammation and that some thin bloody pus was present in the peritoneal cavity. The lower lobe of the right lung showed many small areas of consolidation. The intestinal walls showed no ulceration, no gastric ulcer was found, and the pancreas and kidneys appeared normal to him. The remainder of the examination revealed nothing abnormal. This case occurred under conditions that rendered it impossible for me to study it in a satisfactory manner from a clinical, pathological, or bacteriological standpoint. The few facts, that we know concerning it suggest that it might have been one of idiopathic peritonitis.

There is considerable doubt, in the minds of some men, whether such a condition as primary peritonitis occurs. Terminal peritonitis, occurring in patients suffering from chronic diseases, is not uncommon; but primary virulent infection of the peritoneum of a healthy individual is certainly rare—if it ever occurs.

Martin reports a case of peritonitis that occurred in a man who yearly, for ten years, had had some manifestations of rheumatism. The man died of peritonitis after being ill two days and no obvious cause could be found to explain this rapidly fatal infection of the peritoneum. This case is generally spoken of as one of rheumatic peritonitis. Fifteen recorded cases of rheumatic peritonitis have been collected by Spillman and Vanzinotty. Some of these cases were rheumatic; nine of the patients died. None of them will stand critical examination. It is possible that the case herewith reported was one of rheumatic peritonitis. Salicylate treatment was not used.

Influenza is occasionally mentioned as a cause of peritonitis. Ameiss (*American Journal Obstetrics*, April 4, 1899) believes that influenza may be followed by peritoneal involvement. There is no reason for believing that influenza played any part in causing the death of the patient whose case I have described. It is true that he complained of respiratory symptoms, but these did not correspond to the symptoms of influenza and no cases of influenza had occurred in the locality where the patient lived.

I do not believe that the lung involvement, in the case herewith reported, was the cause of the peritonitis. The abdominal symptoms were well developed before the respiratory symptoms appeared and there was no evidence, at operation or post mortem examination, to show that infection had extended to the peritoneum from the lungs.

There are cases of acute peritonitis reported, where the pathological changes in the peritoneum have been due to bacterial invasion and where no infection atrium could be determined. S. West (Clinical Society Transactions xlx 1896, p. 36); and Watson Cheyne and Southam (*Medical Chronicle*, July, 1892, p. 217) have recorded examples. In cases of this character, it is probable that the microorganisms causing the peritonitis came from the intestinal tract. H. P. Hawkins (St. Thomas' Hospital Reports, 1892) has found microscopical abscesses in the walls of appendices that appeared normal to the naked eye. He believes that the appendix is responsible for some of the cases of so-called idiopathic peritonitis. If this had been the condition, in the case herewith reported, the peritoneum in the region of the appendix should have been more involved than that in more distant parts of the abdominal cavity. This was not the case.

The most plausible theory to explain so-called idiopathic cases of peritonitis is that the microorganisms pass through the intestinal wall, without producing any observable lesion, and attack the peritoneum.

Werden (*Archives des Sciences Biologiques*, St, Petersburg, Bd. 11, 5, 1894) claims that infection of the bladder may take place from the intestines, and succeeded in producing cystitis, in animals, by occluding the rectum and the urethra. Reymond (*Annales des Maladies des Organes Genitourinaires*, April, 1893) has shown that, in dogs, the uro-bacillus liquifaciens of Krogius is not only capable of penetrating the bladder wall but can, also, pass through the intact peritoneum without producing any microscopical lesion.

Infection of the peritoneum from the intestinal tract, seems to be the most reasonable explanation for the occurrence of the peritonitis in the case herewith reported.

A CASE OF MATERNAL IMPRESSIONS.

By HUGH B. CAFFEY, M.D.

Mrs. B., aged twenty-two years, married eleven months, became pregnant about January 1, 1901, and miscarried on July 6 of the same year. On March 6, 1901, her husband. who was a coal miner, was brought home to her with his back broken by falling slate while at work. Upon his arrival at the house, Mrs. B., in her excitement, threw her arms around him and when they were removed, the right one was stained with blood, the sight of which caused her to faint. The husband was completely paralyzed below the waist, and bedsores soon developed on the back, the buttocks, calves of the legs, and heels. Mrs. B. was constantly with her husband and had full care of him, dressing his bedsores, etc.

As previously stated, she miscarried on July 6 (four months after the injury to Mr B.) The child was a male, weighed about five or six pounds, and lived at least twenty minutes. There was a distinct ridge on the back just about where the father's back was broken and had partially united; there were almost perfect bed-sores, corresponding to those of the father; its right arm was splotched with blood spots the same as the mother's had been; and one of the father's feet had a peculiar tendency to turn out, which was also very noticeable in that of the child after it was laid out.

The points of special interest in this case are (1) the number of marks and their perfectness as to location and extent, and (2) the time at which the impressions must have been made, about the second month of pregnancy.

CHLOROSIS IN A CHILD NINE YEARS OLD, COMPLICATED WITH ESTIVO-AUTUMNAL MALARIA.

By E. M. SILL, M.D.,
NEW YORK CITY.

ASSISTANT ATTENDING PHYSICIAN TO BELLEVUE AND THE NORTH-WESTERN DISPENSARIES, CHILDREN'S DEPARTMENT.

B. A., nine years of age, was brought to me complaining of pain in the abdomen, loss of appetite, and constipation, and for the past two months she had had irregular chills and fever, with drowsiness and headache.

On physical examination I found marked pallor of the skin and mucous membranes, tongue somewhat coated, facial expression dull, and spleen slightly enlarged and quite tender.

A microscopical examination of the blood was made, and the malarial parasite of the estivo-autumnal variety was found. There was punctate hæmophilic degeneration of some of the red blood corpuscles, with "brassy" corpuscles, marked poikilocytosis, nucleated red blood cells, etc., with 39 per cent. hæmoglobin and the red blood cells numbering 5,030,000, showing it to be a decided case of chlorosis.

Holt of New York and Rotch of Boston say chlorosis occurs in young girls about the age of puberty, but Taylor, in "Keating's Encyclopedia of Children's Diseases," tells us it can occur under the age of twelve years.

This seems to me to be a primary chlorosis, and not secondary to the malaria, as, if it had been due to the malaria there would have been a destruction of the red cells and consequent diminution of their number, although Marchiafava and Bignami admit that mild paroxysms of malaria, when properly treated, may fail to reduce the number of red cells, "yet such cases must be exceedingly rare.'

Craig, in his work on estivo-autumnal malaria tells us there is a progressive loss of hæmoglobin in the tertian form.

Possibly this might have been one of the rare cases of secondary anæmia, but certainly the combination of symptoms and the age of the child make the case of interest.

The child had had no previous treatment, but was then put on iron, quinine and arsenic, and is now improving rapidly.

SUPERHEATED COMPRESSED AIR IN THE THERAPEUTICS OF CHRONIC CATARRHAL OTITIS MEDIA.

By GEORGE W. HOPKINS, M.D.,
CLEVELAND, O.

Superheated air as an agency in the treatment of chronic catarrhal otitis media in some of its most obstinate forms has long since passed the experimental stage. The claims made for it by the author in a recent issue of this journal (June 1, 1901) were based upon four years of experimenting with this treatment upon a number of typical cases. That superheated air will yield a varying, and, at times, remarkable degree of improvement, when skilfully employed in suitable cases, in conjunction with such other measures as may be indicated, there can be no doubt.

The chief obstacle to its successful employment has always been the fact that it was difficult to introduce superheated air into a cavity like the ear, which would not permit the free passage of a current of hot air to its "blind end"—the membrana tympani—where the heat was most needed. Before the desired temperature could be secured at the tympanum the heat would become unbearable on the auricle. Most of the heat was, of necessity, wasted, and any hot air which reached the tympanum merely reached it accidentally, so to speak.

The natural obstacle in this direction was increased in magnitude by the necessity for packing the canal with gauze to prevent burning. Nor could these obstacles be overcome by employing a different heater of the prevailing type. All of the heaters now manufactured, to the knowledge of the author, are of the "natural-draft" type, in which most of the heat must, of necessity, be wasted in order to secure perfect combustion, and if any attempt be made to drive the heat through any resistance, such as a closed cavity, like the ear affords, the heat will immediately travel in a volume through paths of less resistance—the draft holes. Consequently we are powerless to direct the heat where we would, at will.

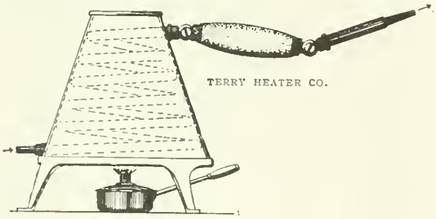

Fig. 1.

This obstacle may be overcome, in a small way, by perforating the "sleeve," or conductor, freely near its distal end, but, at best, even this constitutes a very crude form of treatment.

Nevertheless, despite these readily apparent disadvantages, the old heating appliances and old methods have yielded such splendid results as were never attainable by other agencies.

A far better way has been found, however, and it is made available by a heater recently constructed for the author, along entirely different lines. This heater has been made for me in three types, as illustrated, deriving their heat, respectively, from alcohol, gas, and electricity, the choice of instruments depending upon convenience.

The heater, in its various types, derives its superiority from the fact that it heats compressed air and delivers it to the patient, under pressure, at the desired point only, and the air cannot escape at any other point.

The alcohol heater (Fig. 1) consists of a metal cone, around the inside of which is wound a tapering coil of copper tubing. Beneath it is an alcohol lamp, which heats the coil to a high temperature in a few minutes.

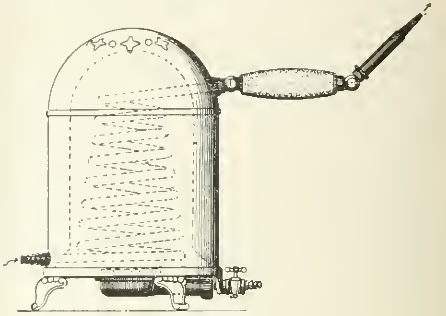

Fig. 2.

Compressed air from a tank, pump, or bulb enters the heating coil at the bottom, through rubber tubing, and leaves it at the top through a metallic tube having an ear-tip of vulcanized fiber, shaped similarly to an ear speculum.

The delivering tube has two rotating joints, which make it readily adaptable to any position of the patient, and the vulcanized fiber ear-tip does not become inconveniently hot, even when the hottest air is passing through it. This heater is far superior to those of the old type, but has a much smaller capacity than either the gas or the electric heater of the new type.

The gas heater (Fig. 2) consists of a blue-flame heater, over which is set a similar, but larger coil of copper tubing. The compressed air enters and leaves the coil in the same manner. It has a large capacity, is economical in cost of operation, and gives splendid results.

The electric heater (Fig. 3) is the ideal appliance of this ideal type. It takes the current from the 110-volt lighting circuit through an ordinary lighting socket and plug, and can be used on either the direct or the alternating circuit. It consists of an air-tight cylinder, holding within it the electric heating

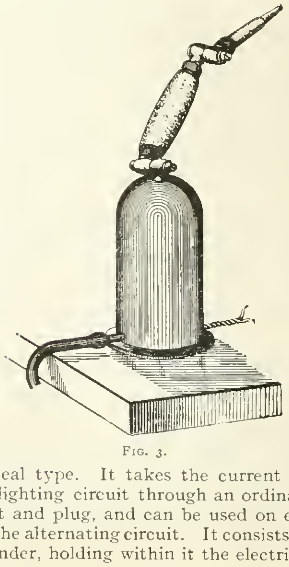

Fig. 3.

wire coil (Fig. 4). A nickel-plated hood surrounds it and the intervening space is packed with asbestos. The wires enter the cylinder at the bottom through a bushing, and, as the cylinder is perfectly air-tight, it serves the purpose of a coil of copper tubing, and makes the latter unnecessary.

Compressed air enters the cylinder at the bottom and leaves it at the top in a manner similar to their other heaters of this type. Air passing through this appliance acquires its maximum temperature in eight minutes—a rate of elevation which is just about right—and the heater is an ideal one in every respect.

With either the gas or electric apparatus an enormous volume and degree of heat can be secured at will. The results secured by employing a heater of this type are incomparably better than the good results secured from heaters of the old and crude type. Heaters of the new type have a direct, definite, and positive action. They embody safety and convenience in every detail and yield certain results, because the compressed air which they heat must escape, with more or less force, at the exact spot desired and cannot escape at any other point.

So great is this advantage that compressed air heaters will, perhaps, ultimately entirely replace the old "natural-draft" heaters.

Several seemingly peculiar facts must be borne in mind in employing compressed-air heaters: (1) When the appliance becomes hot and air exit is through a small opening, as in an ear tip, the temperature of the air is proportional to the rate of flow or degree of air pressure. Strange as it may seem, the air temperature may be increased one hundred degrees by increasing the air pressure five pounds, or, conversely, the temperature may be decreased by lowering the pressure. This fact enables us to regulate the temperature at will by merely increasing or decreasing the volume of air entering the heater; (2) The air temperature drops very rapidly after the air leaves the exit-nozzle, and in order to secure the maximum heat the part under treatment must be as near the nozzle as possible and still allow room for escape of the used air, if a blind cavity like the ear is under treatment.

As to the results which may reasonably be expected from the judicious and skilful employment of this agency with good appliances in cases of chronic catarrhal otitis media, it may be said:

1. That as an exclusive treatment it is rarely of much value in bad cases.

2. That when indicated and judiciously employed, in conjunction with other measures of recognized value, it will give results which would be utterly impossible without its aid.

3. That when employed with care it is absolutely safe unless contraindicated.

4. That it is of little value in old subjects who have extensive labyrinthine involvement.

5. That it stimulates absorption of articular deposits, removes atrophy, and relieves rigidity of the tensor tympani.

6. That it acts more favorably on the ossicular chain than on many other articulations, because of their exceptional proximity to the surface.

7. That arteriosclerosis, serous effusions into the tympanum, and perforations of the tympanum are usually contraindications, and always contrai. indications to the inexperienced operator.

Technique.—The ear selected for treatment is carefully examined and found to be perfectly clean and dry. A light pad of gauze (two thicknesses) is placed over the ear, and with an ear speculum the gauze is pressed deeply into the canal. The ear-tip of the heater is then carried well into the canal, leaving only room enough between the tip and the tympanum for the escape of the used air.

The electricity is then turned on, or the gas ignited (as the case may be), and the compressed air is admitted to the cylinder under about five pounds' pressure. It is well to give a ten or fifteen-minute séance, increasing the temperature gradually until the limit of toleration is reached. The temperature steadily increases without further adjustment until the heater reaches its generating limit at that air pressure, and if the patient tolerates the temperature well, it may be further increased by raising the air pressure to seven, eight, or even ten, pounds in most cases. One cannot be guided by thermometers in giving these treatments, and hence they are not employed on the new heater described. The only guide which can safely be followed is the individual toleration of the patient. But it is well to remember that the more slowly the temperature is raised, the higher temperature the patient can endure without discomfort.

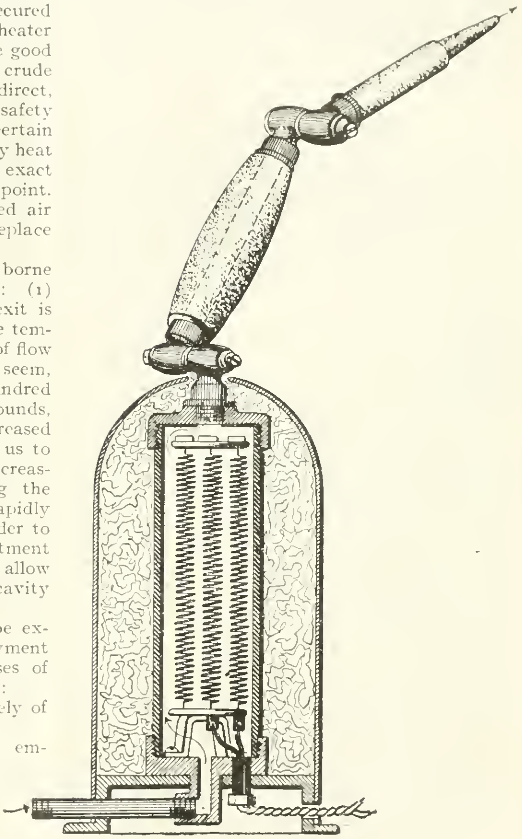

Fig. 4.

Treatments are best given three times a week for from three to twelve months.

Every case must be treated as a whole. He who neglects the appropriate treatment of the nasopharnyx is doomed to disappointment.

Antiseptic washes must be used. All abnormal conditions must be rationally treated. Constitutional measures, when indicated, must not be neglected. Inflation of the Eustachian tube with a warm stimulating vapor from some good apparatus is usually imperative.

It is well to practise Eustachian inflation and vibratory massage of the middle ear with medicated vapor from the vaporizer after each hot-air treatment, being particular that the vapor is warm. A warm vapor is easily secured by connecting the compressed air heater in series with the vaporizer, sending the compressed air first through the heater and then through the nebulizer.

Attention to all detail brings most gratifying success.

A gradual and continuous improvement in hearing and relief of tinnitus may be expected under these circumstances.

A single detail neglected may cause absolute failure.

Cerebro-spinal meningitis	..	2

The Milk Commission of the Medical Society of the County of New York.—The following detailed account of the work of the Milk Commission is published in the *Archives of Pediatrics*: The commission, which has now been in existence for some two years, was given the possibility of success by the coöperation of the Rockefeller Research Fund, which aided this work at an expense of fifteen hundred dollars. It was originally designed to attempt to improve the quality of some of the better supplies of milk in New York. It has gradually broadened its scope, so that now it is controlling a considerable amount of bottled milk sold in New York, and is, moreover, supported entirely by the dairymen who benefit by its labors. The commission, consisting originally of four members, was enlarged in December, 1901, by the addition of six other members, the active work of the commission being deputed to an executive committee of five. The members of the commission are Drs. Walter L. Carr, Henry D. Chapin, Abraham Jacobi, Alexander Lambert, Wm. P. Northrup, Wm. H. Park, Geo. M. Swift, Joseph E. Winters, Edward K. Dunham, Chairman, and Rowland G. Freeman, Secretary.

Two grades of milk come under the supervision of this commission. The lower grade is termed *inspected milk;* this milk is designed to be produced in a cleanly and sanitary manner without imposing upon the producer any expensive care which was not considered absolutely necessary. The requirements for the production of this milk are stated below, and it will be observed that a good quality is insured by the requirement of 4 per cent. butter-fat, while a hundred thousand bacteria are allowed in summer and sixty thousand in the winter months. This bacteriological standard is merely tentative: it is believed it can be considerably reduced. It should also be observed that the granting of the certificate for inspected milk depends upon an inspection of the dairy by the commission's inspector as well as the bacteriological examination of the milk, and that both the inspection and the bacteriological examination must be satisfactory in order that a certificate be granted. The requirements for inspected milk are as follows:

1. The Barnyard: (*a*) It must contain no manure in summer and none in contact with the stable in winter. (*b*) It must be well drained and kept reasonably clean.

2. The Stables: (*a*) The ventilation and light must be sufficient for the number of cows stabled, so that the barn shall be light and the air never close. (*b*) The floor shall be of wood or cement. (*c*) The ceiling shall be tight, if a loft above is used. (*d*) Basins, hand brushes, clean water, soap and clean towels shall be provided in the barn or adjacent dairy room. (*e*) The stable shall be whitewashed in the fall, and in the spring if necessary. (*f*) A sufficient number of lanterns shall be provided to allow the milking to be carried on properly. (*g*) Clean the ceiling and sidings once a month. (*h*) The beddings shall be shavings, sawdust, dried leaves, cut straw, or other material that meets with the approval of the commission. (*i*) The soiled bedding must be removed daily. (*j*) The manure must be removed daily from the stalls and open manure gutter. If a covered manure-gutter is used, it must be kept in a sanitary condition. (*k*) The application of land-plaster or lime on the floor daily is recommended. (*l*) Sweep the entire floor outside of the stalls daily at least an hour before milking is begun.

3. Water Supply: Pure water must be used for all purposes. It must be accessible and abundant.

4. The Cows: (*a*) Discard milk containing mucus or blood and that from any diseased cow. (*b*) Reject milk from any animal forty-five days before and six days after calving. (*c*) The food given must be suitable both in amount, and kind and must not give a disagreeable flavor to the milk. (*d*) Keep the cows clean on flanks, belly, udder, and tail. (*e*) Clip long hairs about udders, and clip the tail sufficiently to clear the ground. (*f*) The cows must be kept from lying down between the cleaning and milking. The best means of accomplishing this is by throat latches. (*g*) Clean the udder thoroughly before milking.

5. The Milkers: (*a*) No milker or assistant shall have any connection with the milk at any stage of its production if he has any communicable disease, or if he has been exposed to scarlet fever, diphtheria, typhoid fever, or smallpox. (*b*) After having everything prepared for milking, thoroughly wash the hands with soap, water, and brush, so that they may be clean when milking is begun. (*c*) The hands and teats must be kept dry during milking. If they become moistened with milk, they must be wiped dry with a clean towel. (*d*) Suitable clean outer garments, such as overalls and jumpers, must be put on before milking.

6. Utensils: (*a*) Strainers, whether metal, gauze, or cotton, must be absolutely clean when used for straining milk. (*b*) All dairy utensils must be absolutely clean and free from dust.

7. The Milk: (*a*) The milk must not be adulterated in any way. (*b*) It must average 4 per cent. of butter-fat. (*c*) Cooling must be begun within thirty minutes after the milking. The temperature of the milk must be reduced to 55°F. within two hours after milking, and to 50°F. within three hours, and kept below that temperature until delivered to the consumer. (*d*) When delivered to the consumer the milk must not average over 100,000 bacteria per cubic centimeter from May 1 to September 30, and not over 60,000 bacteria per cubic centimeter from October 1 to April 30. If the commission's requirements are fulfilled, the bacteria will not be in excess of the number permitted.

8. Inspections: (*a*) The farms which furnish "Inspected" milk must always be open to inpection by the commission. (*b*) Samples of milk must be regularly submitted for bacteriological examination once a month.

Some of this milk may be bought in New York at wholesale for about five cents a quart, while at retail it sells in bottles for eight cents a quart, the ordinary price for milk that is produced without scientific supervision

A higher grade of milk called *certified milk* may also receive the approval of the commission. In order to receive this label the dairyman must produce milk containing, on the average, not more than thirty thousand bacteria per c.c., he must carry out all the precautions required for the production of inspected milk, and must also sterilize all dairy utensils before each milking, must remove the manure from the stalls twice daily, must groom each cow daily, and wipe the udder with a damp cloth before each milking. The full requirements for the production of this milk are as follows: (1) The Barnyard The barnyard should be free from manure and well drained, so that it may not harbor stagnant water. The manure which collects each day should not be piled close to the barn, but should be taken several hundred feet away. If these rules are observed not only will the barnyard be free from objectionable smell, which is always an injury to the milk, but the number of flies in summer will be considerably diminished These flies in themselves are an element of danger, for they are fond of both filth and milk, and are liable to get into the milk after having soiled their bodies and legs in recently visited filth, thus carrying it into the milk. Flies also irritate cows, and by making them nervous reduce the amount of their milk.

2. The Stable: In the stable the principles of cleanliness must be strictly observed. The room in which the cows are milked should have no storage loft above it; where this is not feasible, the floor of the loft should be tight, to prevent the sifting of dust into the stable beneath The stables should be well ventilated, lighted, and drained, and should have tight floors, preferably of cement. They should be whitewashed inside at least twice a year, and the air should always be fresh and without bad odor. A sufficient number of lanterns should be provided to enable the necessary work to be properly done during dark hours. There should be an adequate water supply and the necessary wash-basins, soap, and towels. The manure should be removed from the stalls twice daily, except when the cows are outside in the fields the entire time between the morning and afternoon milkings. The manure gutter must be kept in a sanitary condition, and all sweeping and cleaning must be finished at least twenty minutes before milking, so that at that time the air may be free from dust

3. Water Supply: The whole premises used for dairy purposes, as well as the barn, must have a supply of water absolutely free from any danger of pollution with animal matter, and sufficiently abundant for all purposes and easy of access.

4. The Cows: The cows should be examined at least twice a year by a skilled veterinarian Any animal suspected of being in bad health must be promptly removed from the herd and her milk rejected Never add an animal to the herd until it has been tested with tuberculin and it is certain that it is free from disease. Do not allow the cows to be excited by hard driving, abuse, loud talking, or any unnecessary disturbance. Do not allow any strongly flavored food, like garlic, which will affect the flavor of the milk, to be eaten by the cows Groom the entire body of the cow daily. Before each milking wipe the udder with a clean damp cloth, and when necessary wash it with soap and clean water and wipe it dry with a clean towel Never leave the udder wet, and be sure the water and towel used are clean If the hair in the region of the udder is long and not easily kept clean, it should be clipped. The cows must not be allowed to lie down after being cleaned for milking until the milking is finished A chain or rope must be stretched under the neck to prevent this All milk from cows sixty days before and ten days after calving must be rejected.

5. The Milkers: The milker should be personally clean He should neither have nor come in contact with any contagious disease while employed in milking or handling milk In case of any illness in the person or family of any employee in the dairy, such employee must absent himself from the dairy until a physician certifies that it is safe for him to return. Before milking, the hands should be thoroughly washed in warm water with soap and a nail brush and well dried with a clean towel On no account should the hands be wet during the milking. The milking should be done regularly at the same hour morning and evening, and in a quiet, thorough manner. Light colored washable outer garments should be worn during milking. They should be clean and dry, and when not in use for this purpose should be kept in a clean place protected from dust. Milking stools must be kept clean. Iron stools, painted white, are recommended.

6. Helpers other than Milkers: All persons engaged in the stable and dairy should be reliable and intelligent. Children under twelve years of age should not be allowed in the stable during milking, since in their ignorance they may do harm, and from their liability to contagious diseases they are more apt than older persons to transmit them through the milk.

7. Small Animals: Cats and dogs must be excluded from the stables during the time of milking.

8. The Milk: The first few streams from each teat should be discarded, in order to free the milk ducts from milk that has remained in them for some time and in which bacteria are sure to have multiplied greatly. If in any milking a part of the milk is bloody or stringy or unnatural in appearance, the whole quantity of milk yielded by that animal must be rejected, if any accident occurs by which the milk in a pail becomes dirty, do not try to remove the dirt by straining, but reject all the milk and cleanse the pail. The milk pails used should have an opening not exceeding eight inches in diameter Remove the milk of each cow from the stable immediately after it is obtained to a clean room and strain it through a sterilized strainer. The rapid cooling of milk is a matter of great importance. The milk should be cooled to 45 degrees within one hour. Aeration of pure milk beyond that obtained in milking is unnecessary. All dairy utensils, including bottles, must be thoroughly cleansed and sterilized. This can be done by first thoroughly rinsing in warm water, then washing with a brush and soap or other alkaline cleansing material and hot water, and thoroughly rinsing. After this cleansing, they should be sterilized with boiling water or steam and then kept inverted in a place free from dust

9. The Dairy: The room or rooms where the bottles, milk pails, strainers and other utensils are cleaned and sterilized should be separated somewhat from the house, or when this is impossible have at least a separate entrance, and be used only for dairy purposes, so as to lessen the danger of transmitting through the milk contagious diseases which may occur in the home. Bottles, after filling, must be closed with sterilized discs, and capped so as to keep all dirt and dust from the inner surface of the neck and the mouth of the bottle

10. Examination of the Milk and Dairy Inspection: In order that the dealers and the commission may be kept informed of the character of the milk, specimens taken at random from the day's supply must be sent weekly to the Research Laboratory of the Health Department, where examinations will be made by experts for the commission, the Health Department having given the use of its laboratories for this purpose. The commission reserves to itself the right to make inspections of certified farms at any time, and to take specimens of milk for examination. It also reserves the right to change its standards in any reasonable manner upon due notice being given to the dealers

This certified milk is sold by the different poducers to consumers at prices varying from ten to twelve cents a quart.

The work of the commission is for the most part done by one inspector paid by the commission, who visits the dairies, renders a typewritten report on the conditions found, examines the milk bacteriologically under the supervision of Dr. William H. Park, at the research Laboratory of the Health Department.

The charges made to the farms furnishing certified milk vary from eight to fifteen dollars per month, while the farms furnishing inspected milk, being usually in groups surrounding a creamery, pay only a dollar a month and certain expenses.

Concerning the success of the work of this commission, it may be stated that the dairymen who have been producing milk under the supervision of the commission appear to be well satisfied with the increase in business and higher price which they receive for the milk on account of the security offered to the consumer by the certificate, and have all apparently paid gladly the monthly fee charged by the commission. At the present time twelve dairies, representing 600 cows, are producing certified milk, while five dairies, representing 700 cows, are producing inspected milk. Several dairies have applied for the certified grade and several for the inspected, who are now improving their dairies so that they may be considered satisfactory by the commission.

The Use of Narcotics in the Treatment of Insomnia in the Early Stages of Insanity.—Dr. Henry Rayner has published a paper on this important subject in the July number of the *Journal of Mental Science*. The fact that the deprivation of sleep produces more distress and a more speedy fatal termination than deprivation of food is proof of the predominant need of sleep by the brain and body. In cases of insomnia of some duration there is, says Dr. Rayner, a general disorder of nutrition, and this is nowhere more marked than in the cases of incipient or threatened insanity in which wasting rapidly follows upon insomnia. The drugs generally used in procuring sleep, such as morphia, chloral, and sulphonal, adds Dr. Rayner, have an injurious effect on the nutrition of the body, and their dosage has to be increased to secure sleep if the drug has to be used for protracted periods. Such disadvantages, however, can be avoided by using prolonged baths and gentle massage as a sedative and hypnotic measure, as they not only induce sleep but improve bodily nutrition by promoting elimination of waste products. Narcotics, it is also argued, depress the cardiac, vasomotor, and respiratory centers. The beneficial effects of narcotics, however, appear to be undoubted, but these effects are regarded by Dr. Rayner as being obtained at the expense of the brain, the nutrition of which gets slowly impaired by the use of narcotics. "My individual experience has led me gradually to discard the use of narcotics altogether in narcotic dosage, and to use them only at rare intervals in the hypnotic form, and then only in the form of bromide or of alcohol." Dr. Rayner points out that many practitioners are too prone to use morphia or opium when insomnia exists, and that the temporary benefit which follows as regards the restoration of sleep is often neutralized by the injurious after-effects resulting from the use of this drug. In the discussion which followed the reading of the communication at a general meeting of the Medico-Psychological Association in London, Dr. G. Fielding Blandford stated that the use of hypnotics was often imperative in the insomnia of early or threatened mental disorder, and that the benefit was very great and material., Paraldehyde had in his experience always proved a safe and excellent hypnotic. Dr. G. H. Savage emphasized the importance of procuring sleep in such cases if the threatened mental breakdown was to be averted, and stated that opiates and hypnotics were absolutely necessary. Hydrotherapy also was a valuable aid to procuring sleep in restless and agitated patients, and where mental distress was extreme he had seen the best results follow the administration of large doses of narcotics. Dr. Fletcher Beach concurred in the view that hypnotics, especially sulphonal, were beneficial in cases of insomnia, whether from nervous or mental disturbance, but he thought that a proper diet was also an adjunct to sleep.—*The Lancet.*

Ballooning for Anæmics.—Dr. Naugier of Paris, in a paper read at a recent meeting of the Académie de Médecine, made astonishing claims as to the tonic and blood-forming effects of balloon ascensions. A two hours' voyage in the air, he declared, causes a marked increase in the number of the red corpuscles, and the condition persists for ten days after an ascension. Five such ascensions in the course of six or seven weeks, he said, are more beneficial to an anæmic than a sojourn of three months in the mountains. The good effect begins to be felt almost immediately, and a lengthened stay in the air is of no value, and in the case of many is actually detrimental in causing nervous irritation.

Dr. Naugier urged that the municipal council be asked to provide a large balloon, capable of taking to the upper air daily fifty patients who are too poor to afford a change of climate.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S Marine Hospital Service, during the week ended August 30, 1902·

THE SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE.

By J. A. SCHMITT M.D.,
NEW YORK.

MODERN medicine develops a growing tendency to take diseases out of the hands of the physician and assign them to the domain of the surgeon. Cholelithiasis and appendicitis, for instance, formerly exclusively treated by internal medication, have gradually become favorite objects for operative procedures. It is not mere recklessness, relying on antisepsis, that prompts surgical interference, but the commendable desire to help where medical treatment has not availed. It would be erroneous to believe that the responsibility is simply shifted from one branch of medicine to the other; on the contrary, the physician has the more to exhaust his diagnostic resources and to 'refine his ability of discrimination in order to determine the expediency of an operation. In the diseases mentioned above, the presence of some tangible object, of some pathological substratum, as of a stone or of pus, renders the propriety of surgical measures evident. There is, however, a group of diseases in which the benefit of an operation has been discovered accidentally and in a strictly empirical way. Laparotomy, undertaken for removal of a supposed ovarian cyst, revealed instead a tuberculous peritonitis, the subsequent cure of which was ascribed to the surgical intercession. Abdominal section for peritoneal tuberculosis has now become a well-established method of treatment, although the explanation of its curative effect is based on hypothetical propositions.

The history of surgical treatment of chronic Bright's disease offers similar features; it is both interesting and instructive to follow the development of the idea that renal disturbances, which have heretofore been considered the exclusive province of the physician, could be successfully attacked by surgical means. R. Harrison,[1] in 1896, reported a few cases in which he laid bare the kidney under the impression of finding a calculus or pus. An exploration failed to discover any obvious cause for the symptoms, which consisted of colicky pains, hematuria, and albuminuria. He was surprised, however, to find that the operation was followed by a disappearance of all the symptoms and a final complete recovery of the patients. He attributed the symptoms mentioned to an increased intrarenal tension consequent upon congestion and inflammation within the kidney. He[2] advocated, as a means for relief, either renipuncture or division of the renal capsule proper—capsular nephrotomy—under the following conditions: (1) Suppression of urine with alarming symptoms, as in scarlatinal nephritis; (2) Progressive signs of kidney degeneration, as shown by the persistence or increase of albumin; (3) Where a marked disturbance of the heart and circulatory apparatus arises in the course of inflammatory renal disorders.

Although Mr. Harrison is of the opinion that both kidneys are usually involved, he considers a division on one side sufficiently effective, as "the sympathies existing between the two organs are such as to cause impressions exercised upon one to be reflected on the other; the relief of tension in one organ aids the other; it restores the balance of the urinary excretion when this has been diminished or entirely suppressed."

A somewhat different standpoint is taken by Dr. J. Israël[3]. In a number of cases where renal hematuria and colicky pains were fruitlessly subjected to medical treatment, he cut down upon the kidney, to which the disturbances had been referred, in anticipation of a stone or new growth. Instead of finding the suspected cause, he discovered various inflammatory processes, sometimes involving isolated portions of the kidney, and then, again, the whole organ in the form of a diffuse interstitial or parenchymatous nephritis. As a result of the operation, the majority of the patients were relieved, not only of hematuria and colic, but also of other concomitant nephritic symptoms, as albuminuria, scanty excretion of urine, and frequent micturition.

Israël[4] distinctly disavows any intention to treat nephritis or chronic Bright's disease surgically; he attacks these diseases only when they give rise to otherwise intractable symptoms of hematuria and colic, which, furthermore, must be traceable to one side only. He contends that the favorable influence of the renal division upon inflammatory renal processes, whatever their nature may be, could be satisfactorily explained by the relief of the organ from congestive swelling and increased tension. Increased intrarenal pressure, brought about by congestive swelling within an unyielding capsule, interferes with and even suppresses blood circulation and urinary excretion. He explains the disappearance of all the renal symptoms, though only one kidney has been operated upon, by assuming the existence of a unilateral nephritis.

So far two features in this controversy strike us as novel—first, that chronic nephritis may be unilateral, and, second, that it is curable by operation. There might have been a reasonable doubt as to the true character of chronic nephritis in the cases above reported, but Dr. G. Edebohls[5] of this city dispels any uncertainty by the straightforward announcement that chronic Bright's disease is curable by operation. His deductions are based exclusively upon observations of cases operated upon for movable kidney. He was surprised to find patients, who were afflicted with movable kidney and chronic nephritis at the same time, completely relieved, not only of the symptoms due to the renal displacement, but also of those produced by the nephritis. He drew the conclusion[6] that the displacement of the kidney was directly responsible for the existence of Bright's disease, and that operative correction of the former would cure the latter. He therefore placed chronic nephritis on the list of indications for nephropexy. As a result of further observations, however, he advanced[7] the theory that the curative effect of nephropexy upon chronic Bright's disease is brought about by an adhesive inflammation, which, in establishing collateral circulation, supplies the diseased kidney with new blood vessels. In order to cure Bright's disease it is, therefore, only necessary to create such adhesive inflammation, with consequent vascular connections, artificially by surgical procedure. The presence or absence of renal dislocation is irrelevant, and is of importance only so far as to change the method of operation; in the former nephropexy, in the latter bilateral decortication is resorted to. Dr. Edebohls also dwells on the frequent occurrence of unilateral nephritis. Dr. A. Pousson[8] relates the history of two patients, the one suffering from uræmic attacks, hematuria, and pain, the other from hematuria which led to extreme anæmia. On the latter he performed nephrectomy, on the former, division of the left kidney, which on cystoscopic examination was found to be diseased. From an analysis of twenty-three cases, operated upon by different surgeons, he arrives at the conclusion that surgical intervention—nephrotomy or nephrectomy—may be indicated: (*a*) In chronic nephritis, complicated with hematuria; (*b*) In chronic nephritis, complicated with nephralgia; (*c*) In subacute infectious nephritis; under this head he classes R. Harrison's patients; (*d*) In acute infectious nephritis; miliary abscesses of the kidney and movable kidney with pyelonephritis are comprised in this division.

It may, perhaps, interest the reader to listen to Dr. Pousson's arguments with regard to the unilateral seat of chronic nephritic processes and the favorable influence of surgical intervention upon them. There can be no doubt, he says, that in the overwhelming majority of cases the infectious renal lesions, be they acute or chronic, are bilateral. But is it likewise so at the commencement of the infection? and may this not be gradual? It has been sufficiently demonstrated that bacteria may pass through the kidney without causing any lesion and that they or their toxins exert a deleterious influence only under certain conditions of receptivity of the renal parenchyma. The uneven distribution, the disproportionate degree of the lesions, and the difference of their development may also be features in favor of the unilateral seat of beginning chronic nephritis.

Like Mr. Harrison, Pousson attributes the disappearance of hematuria and nephralgia to the decrease of intrarenal tension after cortical incision. By dividing the rigid capsule proper, the elasticity of the renal parenchyma is restored, the circulation regulated, and the secretion of urine reestablished. He also assumes the existence of a sympathetic nephritis analogous to the sympathetic ophthalmia, and maintains that an improvement of one kidney carries with it an improvement of the other, and a change for the worse on one side reacts on the other in a similar way. The division of the renal parenchyma produces, furthermore, an abundant flow of blood which favors an elimination of microbes and their toxins, removes epithelial ditritus, and thus frees the passage of the tubules for an unimpeded urinary flow. To bring about these beneficial effects for a longer period, a protracted drainage of the renal wound should be maintained.

In a later communication Pousson[9] gives an account of five patients, presenting either the symptoms of parenchymatous or of interstitial nephritis. One died after renal division had been performed; another was suffering from hematuria, pain, and uræmic symptoms, which necessitated nephrotomy of the right kidney; as the Brightic symptoms reappeared a short while afterward, nephrectomy was performed, and three years after the patient's health was perfect. Of more interest are the histories of the last three patients, on whom unilateral nephrotomy with drainage had been performed, for the sole purpose of combating various Brightic disturbances, *i. e.* albuminuria, dyspnœa, vomiting, œdema, associated with a considerable decrease in the amount of urine and urea. One patient appeared well five months after operation.

In the other two cases the symptoms returned, though the beneficial effect of the operation was apparent in the increase of urine and urea, and the disappearance of uræmic symptoms. Two of those patients were presented at the meeting of the "Société de Médecine et de Chirurgie de Bordeaux" on January 31, 1902. The one operated upon July 3, 1901, was in perfect health, and showed only traces of albumin, while the amelioration in the other, operated upon August 1, 1901, was considerable, in spite of the presence of albumin and casts in the urine.

As will be seen from a study of this brief historical account, the idea of operating for chronic Bright's disease was evolved differently: in England, France, and Germany it originated from observations of patients operated upon for renal hematuria and pains; in this country of patients operated upon for movable kidney. Let us now see to what extent we may accept the many reports and explanations as evidence that chronic Bright's disease may be unilateral and curable by surgical measures.

It is an occasion for regret that Dr. Edebohls draws his deductions from observations on movable kidney. Displacement of the kidney may give rise to a variety of disturbances, among which the appearances of albuminuria with casts should be mentioned as having a significant bearing on our subject. Whether it be the result of venous stasis from compression of the renal veins or of urinary retention from kinking of the ureter, is a question in regard to which there is difference of opinion, but all agree that the disappearance of albumin after operative fixation should be credited to this procedure. Even when movable kidney is complicated with true Bright's disease, we may reasonably assume that the displacement constituted a predisposing cause. In this respect Dr. Edebohls[10] himself may be quoted—"If displacement of the kidney gives rise to congestion, why may not the latter condition occasionally progress to inflammation?" And again: "Mobility of the kidney will probably be found as playing a very important part in the causation of chronic nephritis. Just as probably the therapy of chronic nephritis, in so far as the latter be found to be dependent upon and connected with movable kidney, will become surgical." As I indicated above, Dr. Edebohls has since changed his views. Women, generally, with their manifold and often dormant genitourinary disorders are less suitable objects for demonstrating successes in the surgical treatment of chronic Bright's disease. Any inflammatory process in the pelvis is apt to creep along the ureter and extend to the perirenal tissue, causing chronic perinephritis and pyelitis with their sequelæ. When we add to such agencies the occasional infection from the adjacent colon and the disorders within the urinary tract, and consider that any local process, as stone, new growth, or pyelitis, may cause a chronic nephritis, we cannot wonder at the great number and varieties of disturbances which are complicated with albuminuria and casts, but have not the significance of Bright's disease. Coincident diseases, as movable kidney, pelvioperitonitis, hypertrophic prostate, pyelitis, etc., should rather not be utilized, in order to get a clear field for the question to be decided. It is regrettable that so many of the published cases lack in details essential for a correct judgment. R.

Harrison's original reports, for instance, are so painfully deficient in particulars as to leave us in doubt what the real pathological condition of the kidneys might have been. Dr. Edebohls[11] includes in his list of chronic Bright's disease a septic kidney with miliary metastatic abscesses, which everyone who attentively reads the account of Case 18 will recognize as such. His material comprises for the greater part movable kidneys, and the particulars offered in support of Bright's disease leave us too often in the dark as to the real nature of the disorder. It is true, Edebohls verifies the diagnosis "upon the critical test of actual inspection and palpation of the kidney at the time of operation," but we shall discuss later how far we may accept his propositions in this direction.

A. H. Ferguson[12] reports two cases of women, who were operated upon for intense pains referred to the region of the kidney. Decortication afforded relief from pain. A microscopical examination of a section from the cortex of the kidney, removed during operation, showed interstitial nephritis in both instances. Apart from the pains, these patients had no other symptoms of Bright's disease. It is unjustifiable to infer from the microscopical findings of a particle of the cortex the condition of the whole kidney. We may easily be led to the diagnosis of Bright's disease where only a circumscribed focus of inflammation in the cortex is present. R. Guitéra's[13] classes under the head of chronic Bright's disease a case which could more appropriately be designated as pyelonepritis secondary to a prostatic hypertrophy.

In the face of such indiscriminate mixture of all sorts of kidney diseases, it would be well to keep in mind the essential features of chronic Bright's disease. All authorities are now fairly well agreed that it is of hæmatogenous origin, *i. e.* noxious substances, whatever their nature or the cause of their formation may be are circulating in the blood and pass through the kidneys. It depends upon the virulence of the injurious material, the frequency with which it is poured into the current, and the vitality of the renal tissue-cells and the duration of the disease, how serious the renal lesion will be. There is no reasonable ground to suppose that the lesion occurs on one side only, though the intensity of the inflammatory process may be varying in both kidneys and in different portions of the same kidney. The question of the unilateral seat of chronic Bright's disease has been raised by the surgeons to explain the cure of patients who had been operated upon on one side only. Dr. J. Israël cautiously uses the term chronic nephritis. Indeed, many of his cases reveal localized renal inflammation, explainable by local irritation, such as cystitis, perityphlitis, or pelvioperitonitis, and no objection may be made to the use of such a general designation, so long as it is not promiscuously employed for true Bright's disease. In fact, where Irsaël's reports impress us with the existence of Bright's disease, the benefit of unilateral operation was either transient or the autopsies revealed characteristic lesions on both sides. Dr. Edebohls' subjects the kidneys, while they are exposed in the wound, to inspection and touch, and draws the inference that the kidney is healthy when nothing pathological presents itself to these senses. As renal inflammation may have progressed far without any demonstrable surface changes, Dr. Edebohls' assertion as regards the frequency of unilateral chronic Bright's disease cannot be accepted as conclusive. Chronic Bright's disease comprises two principal types, each with distinct and well-outlined features. A brief consideration of these may be the more profitable because of its absence in many reports bearing on the subject under discussion. There is one type in which the urine is scanty, concentrated, of high specific gravity, rich in albumin and formed elements; anasarca, dropsical effusions, and uræmic symptoms are present; the daily amount of urea is lessened; pallor and puffiness give to the face a characteristic appearance. At the beginning circulatory disturbances are absent. We are justified in bringing these symptoms in connection with the presence of a large white or a large red—usually mottled with red and white—kidney. The inflammatory process is diffuse in the double sense of the word: it involves parenchyma and interstitial tissue, and is scattered over the whole organ. Whether the the parenchymatous or interstitial alterations preponderate can only be determined by microscopical examination, as every possible degree of combination between these two may exist. Contrary to Edebohls' contention, the impossibility of inferring the relative extent to which the various elements of the renal structure are involved from the macroscopical appearance of the surface of the kidney must be particularly emphasized. Even in the large white kidney, as Leyden has pointed out, the inflammatory changes of the interstitial tissue may predominate.

Not infrequently the exterior surface of the large white or red kidney presents irregular elevations, due to atrophy of interstitial tissue. Even clinically we may be able to recognize an atrophic stage of the large kidney (secondarily contracted kidney). Anasarca and dropsical effusions disappear; circulatory disturbances and hypertrophy of the left ventricle make their appearance; the urine becomes copious clear, poor in albumin and formed elements, of low specific gravity, and after a longer or shorter period assumes again the changes peculiar to the large kidney. There is another important type of chronic Bright's disease, in which the urine is abundant, clear, pale, of low specific gravity, showing hardly any albumin and formed elements. Anasarca and dropsical effusions, pale and puffy complexion are wanting, but circulatory disorders and hypertrophy of the left ventricle well marked. Uræmic symptoms and retinitis albuminurica are usual accompaniments The daily excretion of urea is lessened. These symptoms correspond with the genuine or small granular kidney. Here also both organs and all the elements of the renal structure are involved, but with the very prominent characteristic that at the onset a cicatrization of the interstitial tissue takes place.

In concluding the sketch I have drawn of the principal varieties of chronic Bright's disease, mention should be made of their frequent coincidence with amyloid degeneration and the modification of the clinical symptoms incident to it. Are we able to differentiate the various types of chronic Bright's disease by ocular and digital examination? To a certain extent and with some restrictions, yes! Formerly our conceptions about the appearance and condition of bodily organs were principally based upon observation after death; modern surgery has placed us in a position to see and feel the living organs in health and disease, although the advantages gained thereby seem to have been exaggerated. Naturally, the method of exploring living organs is restricted, and many a disorder, while thus escaping detection, may be revealed at autopsy by a more exhaustive and a more reliable examination. The above criticism applies with particular force to the inferences drawn from the gross appearance of surgically-exposed kidneys, especially if only deprived of their investment instead of being cleft into halves. Diseased kidneys, it is true, which present characteristic features of the large white or mottled, or the small granular, kidney may be easily recognized as such. If in connection with these changes depressions on the surface or small cysts are demonstrable, deductions as to the shrinkage of interstitial tissue, the constriction and dilatation of sections of the uriniferous tubules may be drawn without meeting objection. But if these changes occur singly and without any other noticeable surface alterations, the utmost caution in interpreting such processes must be exercised. A renal cyst, for example, may occur in otherwise healthy kidneys and be congenital, or the remnant of a previous nephritis which has healed. Similar restrictions should be placed on the explanation of depressions on the renal surface; a previous infarction, a past inflammation upon healing give rise to cicatricial depressions; even shallow fissures, remnants of the fetal construction may be confounded with depressions, due to atrophy of interstitial tissue. Thickening and firm adhesions of the renal capsule proper, with localized discolored areas in the cortex may just as well be the consequence of an inflammation from without as from within. Everybody familiar with the pathology of the kidney will bear me out in the statement that the small granulations in the primarily-contracted kidney are sometimes difficult to distinguish from multiple metastatic abscesses, and these latter again from miliary tubercles; furthermore, it is impossible to decide by mere inspection whether in a given case a grayish white discoloration is produced by a fibrous, amyloid, or fatty degeneration.

A mere surface inspection affords us but little information as to the condition of the kidney substance within; the great number of diseases which originate in the pelvis and the medullary substance is removed from our observation. I mention, for instance, the urate deposits, which occur chiefly in the pyramids, and give rise occasionally to extensive inflammatory processes before any changes are visible in the cortex. In fact, any local process is apt to cause chronic nephritis in the broad sense of the word. To rely on the touch and to deduce from an increased resistance the nature of the intrarenal process involves a great deal of guesswork. From the facts just adduced it is evident that mere inspection and palpation of the kidney may fail to reveal a great number of pathological conditions within, and, on the other hand, lead us to give undue importance to surface-alterations. It must not be forgotten that the surgeon in handling the kidney is frequently hampered in his judgment by the profuse bleeding. The kidney while displaced and exposed on the skin begins to swell and to assume a deep-bluish color and responds to any attempt to strip off the capsule proper with obstinate parenchymatous bleeding, which can be checked only by placing the organ in its place again. At all events it would be more judicious simply to register the pathological findings and to refrain from forming a definite diagnosis from them.

Even after cleavage of the kidney, which doubtless affords a better insight, lesions, if not located in the plane of the incision, may easily escape discovery. Dr. Zondek[14] has convincingly demonstrated that a careful search even after splitting the kidney may fail to reveal the presence of a stone, if this be concealed in an adventitious calyx, and that nothing short of an exhaustive examination of the kidney after removal from the body could succeed in detecting the calculus as the real cause of hæmaturia, pain, and inflammation. Dr. Pels-Leusden[15] reports a case of a woman suffering from renal hæmaturia. On splitting the right kidney, the surface of which appeared perfectly normal, nothing pathological would have been detected if in handling the kidney a small particle had not been accidentally detached, which, on microscopical examination, proved to be a malignant growth. After removal of the kidney, it required a most attentive inspection to detect minute, villous excrescences in the depth of some of the calices. Dr. Edebohls' ingenious theory of establishing an anastomotic circulation through adhesions between the kidney and its surroundings offers so many points for discussion that a brief consideration may be in place. Adhesions with formation of anastomoses cannot be created at the will of the operator; occasionally they are so dense and devoid of blood vessels as to frustrate the purpose of supplying new blood to the diseased organ. And even granted the formation of new bloodvessels, is there any probability that these invade the renal substance and enter into capillary anastomosis with the circulatory sytem of the kidney? What assurance have we that these supposed newly-formed capillaries do not succumb to the same pathological process in which the organ is involved? Besides, numerous sections of the kidney—in the large red, for example—are in a highly congested condition, and do not require an artificial blood-supply, others reveal the glomeruli obliterated, the tubules collapsed, and the different constituents of the organ, as in true granular kidney, in such a state of atrophy as to be beyond repair. The conception of restoring parenchyma thus destroyed to functional activity by artificial blood-supply cannot reasonably be allowed, and the argument to protect a part by surgical interference from without while the noxious material is imported from within, seems to me extremely hypothetical. We might even go further and contend that the kidney, supposing that vascular communications through the adhesions take place, is in greater danger, as it is flooded by deleterious substances from both sides. Dr. Edebohls refers to similar conditions obtained by the operation for cirrhosis of the liver, which consists in the establishment of anastomoses between the omentum and the anterior abdominal wall, and of adhesions between the spleen and the lateral wall, and the upper surface of the liver and the diaphragm. Such adhesions with collateral blood vessels act merely mechanically by relieving the venous stasis in the portal circulation; they have no healing effect whatever on the diseased liver-tissue. No surgeon has so far ventured the assertion that he could cure cirrhosis of the liver by the Telma-Morison operation, he is generally very happy to see, as the result of his interference, the patient relieved from ascites.

Although Dr. Edebohls' views with reference to the surgical cure of chronic Bright's disease require confirmation in many particulars, the impetus he has given to further investigations cannot be too highly valued. Many questions agitated by Dr. Edebohls call for renewed investigations. One of the interesting questions to be determined relates to the formation of adhesions carrying a new blood-supply to the diseased kidney. This could be cleared up by experiments on animals, whose kidneys have been decorticated. After a reasonable time the animal should be killed, the renal and artificial blood vessels be injected, and microscopical sections through kidney and adjacent adhesions be made, to demonstrate the presence of anastomosis in the healthy kidney; like researches, to ascertain such relations in the diseased kidney, could obviously be made only after the death of the patient, on whom decortication for chronic Bright's disease had previously been performed. Another not less instructive but much-mooted question refers to the unilateral seat of chronic Bright's disease. A methodical ureteral catheterization and a chemical and microscopical examination of the separated urines should be made in each case. Hitherto the diagnosis of unilateral chronic Bright's disease has been attempted along various lines. I have previously pointed out that the results of ocular and digital exploration of the living kidneys have only a positive diagnostic value: to declare a kidney healthy because of the absence of any gross alterations on the surface is not permissible. Instances where patients regained their health after unilateral operation have been cited as proof that chronic Bright's disease may afflict only one kidney. But there is little foundation for this notion, autopsies do not confirm it, nor does a careful study of the cases on record: either they can more reasonably be interpreted as being of local origin, or they are only temporarily benefited and assume sooner or later their fatal course.

Only one exception has to be admitted, namely: urate deposits consequent upon "uric acid diathesis." They may even disappear after the betterment of the patient's constitution. But when they cause chronic Bright's disease they present, indeed, additional evidence that this disorder is of toxæmic nature and involves both kidneys.

It is tempting to reason that *incipient* Bright's disease may, perhaps, occur unilaterally and, therefore, be more easily checked by surgical means. It is well known that lesions with functional impairment of the renal organ will give rise to retention of waste products, chemical changes, and impoverishment of the blood, which themselves act again deleteriously on the renal tissue. Thus a circulous vitiosus is created. Is it possible to inhibit the extension of the pathological process to the other side, or, as this question applies with equal force to chronic Bright's disease generally, in which we naturally expect both kidneys to be afflicted, have we any ground for the belief that the progressive character of the disease may be arrested by an early operation? Unfortunately, the majority of cases of chronic Bright's disease start insidiously, with a pronounced chronic and progressive character. Irreparable lesions may have taken place long before the first symptoms come to the notice of the physician; not infrequently an impaired vision or uræmic symptoms are the first signs to attract attention. Surgical intercession would, indeed, frequently be belated without any fault of the practitioner. The best opportunity to follow the development of the disease at the outset is afforded by acute Bright's disease after scarlatina, or any other infectious disease. Such acute cases tend toward recovery even after a considerable time, and the practitioner could hardly be expected to follow any other than conservative plan of treatment. At any rate, the surgeon sees only well-advanced stages, as in practice the physician will recommend operation only as a last resort, when all other expedients have failed.

But let us assume, the surgeon intervenes at an early phase, how many objections against the claim of success may be raised with regard to the possibility of spontaneous cure, of recurrence, of diagnostic errors—in short, with regard to all the questions, intimately connected with the theme under discussion.

In recent years cryoscopy, *i. e.* the determination of the freezing point of the blood serum and urine has been employed as a means to ascertain the functional efficiency of the kidneys in health and disease. These cryoscopic investigations go far to throw light on the present subject and are of sufficient interest to warrant a brief presentation of the essential facts.[16] The freezing point of distilled water is 0° C.; the more concentrated a solution, the lower is its freezing point. Blood serum of a healthy person freezes at 0.56°; urine at from 1° to 2°. In chronic Bright's disease the blood serum becomes more concentrated, and its freezing point is lowered to 0.6° and more. On the other hand, the urine becomes less concentrated and its freezing point is raised, approaching values nearer to zero.* Supposing a person is suffering from some renal disorder, as hematuria, or pain, and presents a blood serum with a freezing point of, let us say, 0.65°, we may justly assume an impairment of the function of both kidneys, although catheterization of the ureters and a separate examination of the urine have, at the time of investigation, shown only one side to be affected. If one urine specimen is normal and the other contains albumin, casts, blood, etc., the diagnosis of a unilateral process as stone, pyelonephritis, or tuberculosis, may positively be made, provided the freezing point of the blood serum is normal. Dr. Kümmell[17] has, on ureteral catheterization, found both kidneys to be implicated in every instance of chronic Bright's disease. Dr. F. S. Strauss[18] arrives at the same conclusions.

I have so far dwelt on the different views as to the surgical treatment of chronic Bright's disease. It remains to inquire whether in fact a case of this disease has definitely been cured by operation. If we take into consideration only such cases where the urine analysis in conjunction with clinical symptoms has established the diagnosis beyond doubt, and if we eliminate those too recently operated as to admit of a conclusive opinion, we may safely assert that a number of symptoms has been relieved, but that chronic Bright's disease, as such, has not been cured by operation, which at best represents only a symptomatic, but never a curative measure. From a study of the published records the following conclusions may be formulated:

1. In acute infectious diseases anuria with uræmic symptoms threatening the life of the patient can be successfully combated by capsular incision or renal cleavage, which relieves congestive swelling and excess of intrarenal pressure. Operation on one side is sufficient to bring about an abundant urinary secretion, followed by a subsidence of the alarming general features. Whether the other kidney gains time to recuperate and reassume its function, or whether reflex action plays a predominant rôle, are debatable points. At all events nature seems to get along with a small portion of functionating kidney tissue.†

2. Anuria with uræmic symptoms, occurring in the course of chronic Bright's disease, has afforded an occasion for surgical procedure. To recognize such an indication on reasons which are analogous to those above mentioned is, of course, a matter of individual judgment. Temporary relief, in some

---

* The freezing point of the urine is normally too inconstant to be of much value.

† Very instructive in this respect is the history Dr. Israel relates of a patient whose right kidney had been removed eight months previously for tuberculosis, and who was suddenly attacked by anuria and uræmic symptoms. The remaining kidney was split and revealed a great number of miliary abscesses; an immense amount of urine was discharged from the wound. The uræmic disturbances disappeared and patient got well again, barring traces of albumin in the urine and frequent micturition.—*Mittheilungen aus den Grenzgebieten der Medicin un Chirurgie*, 1899.

instances, had been gained—a permanent cure, however, has never been effected.

3. When the kidney has been operated upon directly for the cure of chronic Bright's disease the outcome has been a failure. The apparent benefit manifested in the disappearance of dropsy, dyspnœa. etc., occur just as regularly in the ordinary course of the treatment by medication and capillary drainage or puncture.

4. In exceptional cases colicky pains and hematuria are caused by chronic Bright's disease. Capsular incision or cleavage of that kidney to which the disturbances were traceable, has been attended by excellent results; there can be no doubt that, when medical expedients have failed, surgical interference has succeeded in checking the hemorrhages and alleviating the pains, but it does not inhibit the progress of chronic Bright's disease.[19]

5. Nephropexy may cure the ailments incident to movable kidney; it may remove albuminuria, if this be the result of local irritation, consequent upon the displacement; if, however, the movable kidney is affected by chronic Bright's disease, this affliction will remain uninfluenced by operation.

We have seen that surgeons employ different methods of operating. Dr. Harrison is in favor of renal puncture or capsular incision. Dr. Israël advocates renal cleavage, and Dr. Edebohls partial decortication in movable kidney and complete decortication in chronic Bright's disease without displacement. In three cases he claims success even from partial decortication on one side. Each one observed benefit or cure from his particular method, and it would be interesting to find out some common ground, something that is common to all the operative devices and would explain at least the symptomatic success. If I might express an opinion, the success is principally to be attributed to the local bleeding and relief of tension after incising the capsule proper. These two agencies coöperate in easing the intrarenal circulation and urinary flow, and may most effectively be brought into action by renal cleavage, though the subsequent cicatrization is bound to deprive the kidney of a part of its functionating tissue.

It has often been remarked that patients afflicted with chronic Bright's disease are, under any circumstances, doomed, and should, therefore be given every chance medical art may contrive. Not so, however, if the help proffered should prove ineffectual and an additional vexation. To enable the reader to form his own opinion of the correctness of the propositions enumerated above, and to determine for himself the many points in controversy, a careful study of the published reports bearing on the surgical cure of chronic Bright's disease is indispensable. Fortunately, the literature is not very extensive and its perusal, therefor, will not greatly tax our patience, though every case should be scrutinized and decided with reference to the facts under review. Before long the list will be enlarged and the surgical treatment of chronic Bright's disease will probably become fashionable, until mature experience and sober judgment have exposed the fallacy of the proceeding.

WHAT SHALL WE DO WITH OUR CONSUMPTIVE POOR, BEING A DISCUSSION OF DR. KNOPF'S PAPER.

By DR. ALFRED MEYER,
NEW YORK.

UNLESS we wish to include the old Spartan method of destroying the weaklings, there are only two methods open to us in dealing with the consumptive poor. The one would be simply to leave them to their fate, and the other to provide for them such care as would at least give them the ordinary fighting chance of recovery. To leave them to their fate is almost as unethical and abhorrent as to destroy them after the old Spartan fashion; and, as a matter of fact, every civilized community has adopted, at least in principle, the method of providing free care for their consumptive poor. The difficulty the world over has been two-fold; first, that the number of cases to be cared for is so large that the provision for them has been pathetically inadequate, whether aid were extended from the public purse or by private philanthropy; and second, that large numbers are cared for so late that they must needs be classed as hopeless when they present themselves for charitable relief.

The first difficulty, that of inadequate provision, has been growing rapidly less during the past few years. Under the stimulus of Koch's discovery of the tubercle bacillus, of a reduced mortality, international congresses, national and state associations for the combat of tuberculosis, an ever-increasing amount of interest and help has been extended to this class of sufferers. In our own country the movement for State aid has spread with striking and encouraging rapidity throughout the Union, in spite of the twin bugaboos of paternalism and expense. In nearly every community a handful of professional and lay workers have been able to keep up public interest in this large and many-sided question. In this connection it is of interest to note that in Massachusetts, where the first State sanatorium for consumptive poor in the United States was established only three and a half years ago, the results have been so encouraging in the way of cure, improvement, and hygienic education of patients, that there has already been a strong pressure on the legislature to duplicate the institution in another part of the State—a striking contrast to the indifference of the public during the years of agitation that preceded the first appropriation of State funds for this purpose. The trustees, very wisely, I believe, have preferred to enlarge the existing institution from 180 to 250 patients, and by this action have exemplified for the hundredth time that pioneers in great movements are, in the end, the most conservative guides.

The second great difficulty, the advanced and hopeless stage at which many cases begin the active fight for recovery, is also growing less, because of the earlier recognition of the disease by bacteriological methods and by serum diagnosis, the increased number of physicians who are skilled in this special field, the spread among the masses of the knowledge that in its early stages it is a most curable disease, and, lastly, because of the increasing number of sanatoria and the propaganda made for them by discharged patients.

In most particulars I am in perfect accord with the reader of the paper. I wish especially to accentuate the point that a large proportion of cures may be effected without expatriation, without exhausting journeys, without breaking up of families, without great traveling expense, without a complete isolation from those who are dear to us, without the brooding homesickness that comes with the rupture of domestic ties and banishment to distant lands and strangers. The corollary of this position is the one that finally each country may solve its own tuberculosis problem at home, this being true of even the smaller political units, such as states, counties, and large cities. To make this possible the State, municipalities, and private philanthropy must vie with each other in the friendly rivalry of providing:

1. Institutions beyond city limits for the incipient and presumably curable cases of tuberculosis, of which the Bedford Sanitarium of the Montefiore Home is a good example.
2. Institutions within the city limits for advanced and presumably incurable cases, like the Blackwell's Island institution in charge of Commissioner Folks of the Department of Charities, New York City.
3. A series of separate wards in the city hospitals to act as clearing-houses for cases of doubtful diagnosis and prognosis.
4. A system of financial aid to the families of adult patients to encourage early treatment.

Institutions of the first type, sanatoria, if possible should be placed within forty or fifty miles of the great cities. Besides the general consideration in favor of such action, that cases may be cured there, the following should be remembered:

First.—Largest number of cases likely to come from there.

Second.—Convenience of access for physicians and laymen who will be charged with the medical and administrative supervision.

Third.—Nearness to base of supplies.

Fourth.—Special force of the example for the whole anti-tuberculosis movement when such institutions are placed near large cities.

Much may be said in favor of establishing farm gardens and dairies in connection with sanatoria for consumptive poor. They give healthful employment and diversion to the patients, they give them training in and taste for agricultural pursuits and diminish the probability of their return to city tenements, with its attendant danger of relapse. In addition, such employment helps maintenance of discipline among the usually large number of ambulant cases, and very materially assists an economical administration by supplying the institution with the products of the patients' own labor. The cases for such work must be carefully selected by the medical officer of the institution, as also the amount and character of the work assigned to each one, and the effect upon him watched. This method has been tried on a small scale at the Massachusetts State Sanatorium, but nowhere, I believe, on so large a scale as at the Bedford Sanitarium of the Montefiore Home, Westchester County, New York, with which I have the honor to be connected. Two years ago when the institution accommodated only twenty-five patients the following farm products were raised by the patients under the supervision of a skilled farmer: 30 tons of hay, 160 barrels of potatoes, 160 barrels of apples, 70 bushels of onions, 350 bushels of corn, 1,000 heads of cabbage, 25 bushels of beets, 40 bushels of carrots, 100 bushels of turnips, and about twenty other kinds of vegetables. Since the opening of the new buildings one year ago the number of patients has increased to nearly 150, the number capable of doing work has grown in proportion and there has been a considerable surplus of farm products over and above the immediate needs of the institution. These facts appear to me to be of great importance and worthy of a wide dissemination among those interested in both the economic and medical aspects of sanatorium management.

THE PRIMARY TREATMENT OF RAILWAY INJURIES.*

By J. N. BAKER, B.A., M.D.,
MONTGOMERY, ALA.
SURGEON TO THE PLANT SYSTEM OF RAILWAYS, AND ASSISTANT SURGEON SEABOARD AIR LINE R. R.

Mr. President and Gentlemen of the Society: The above title has been chosen for the few remarks to be made before you to-day, because it seems to me that, among a body of men brought together by a common purpose as we are, the discussion of such a topic would not be inappropriate, and to some of us possibly helpful. What follows is not intended to be limited to railway accidents exclusively, but applicable, in the main, to all classes of personal injury, regardless of the manner inflicted; though railway injuries do present some interesting and almost unique features, as will be pointed out later on.

Especially, what is here said concerning *shock*—surgical shock—can be applied to practically all cases of injury of any magnitude; yet in railroad surgery, above all others—and for palpable reasons—we meet with this element most often, manifesting itself in a grave form after an apparently insignificant injury.

What is shock? Within the memory of many of you here to-day—for it has not been so many years since—you look back and recall how vague and misty were your earlier understandings of this subject. Even to-day many of our works on surgery are inclined to treat this subject superficially and briefly; yet it is an important one, and an intelligent handling of it practically is based upon an intelligent conception of its pathology.

Owing to recent researches made by painstaking investigators, aided by the microscope, our ideas of this subject have been materially enlarged and made more accurate, although we do not yet know it all—nor is it likely that we ever will.

When an injury of any gravity is done the body surface we have *shock*—the degree and amount depending upon the violence inflicted. The symptoms of shock are referable to, and explained by, the effect on the *nervous system*, and especially the spinal cord and its sympathetic connections.

---

*Read before the Association of Surgeons of Plant System at their annual meeting in Savannah, Ga.

Pathologists have been able to demonstrate decided changes in the ganglionic cells of the spinal cord—a shrinkage and contraction of the nucleus—with a vacuolation of the protoplasm of the surrounding cell, the same condition that obtains after overstimulation and exhaustion of these cells. In the graver forms of shock the vasomotor centers seem particularly to suffer, and thus we are able to account for the serious derangement of the heart and the circulatory apparatus. Briefly stated, then, it may be said that shock is a state of general depression, reflexly produced by damage done the peripheral nerves and with symptoms referable, in the main, to vasomotor paralysis.

Let us distinguish between surgical shock and collapse, restricting the latter to cases in which serious loss of blood is the causative factor; for it is the exception rather than the rule in railway accidents to have serious primary hemorrhage. If the violence done the part is sufficiently grave to injure the larger vessels, we usually find them sealed, owing to the crushing of their walls.

The symptoms of shock are: a depressed and enfeebled circulation, a lowering of body temperature, a pinched and expressionless countenance, pupils varying, though usually dilated; mental apathy, and a cold and sweaty skin; and in the graver forms a relaxation of the anal sphincter. Should the head be involved instead of mental apathy we may have profound unconsciousness or mental excitability.

In the *treatment* of shock, recalling the fact that the condition is one of nervous depression, our energies should be directed toward arousing this system—both centrally and peripherally. *Centrally* this may be done by the administration of the usual agents familiar to us all, as strychnine, nitroglycerin, brandy, whiskey, aromatic spirits of ammonia, morphine, or atropine; all of which should be given hypodermatically and not by mouth, if the condition be at all serious, owing to the difficulty in swallowing and the uncertainty of absorption from the stomach. Of these agents morphine, either singly or, preferably, combined with atropine, heads the list; the dose should be from ⅛ to ½ gr., sufficiently large to get physiological action. *Peripherally*, this may be done by heat; having the patient well wrapped in blankets; by the free use of hot-water bags to the body surface and by having the temperature of the room more than comfortably warm.

In addition to these we have an agent whose action can be attributed to both its central and peripheral stimulation—namely, the saline infusion. In severe cases of shock where immediate and decided results are desired, the infusion should be given intravenously and not subcutaneously. Let us pause for a moment to consider some of its physiologic actions; for its beauty lies in the fact that much of its action is physiological and mechanical and can thus be understood. Introduced into one of the superficial veins about the elbow and with a proper hydrostatic pressure, the fluid is rapidly dissipated through the veins of the arm into the larger veins of the neck, where, owing to the negative pressure there existing, the fluid will rapidly find its way into the heart, even though the venous circulation be much impaired. Here the nerve terminals in the endocardium and the intrinsic cardiac ganglia receive stimulation, and the heart is thus aroused; the heart being aroused and, at the same time, finding a volume of fluid with which to work, distributes this agent to the various organs and tissues of the body. Thus both the central nervous system is stimulated and likewise the peripheral nerves throughout the body, including the vasoconstrictors of the arterioles, which, as we we have seen, seem to particularly suffer in shock. This combined action of a central and a peripheral stimulation is an important one and does much toward restoring the tone and equilibrium of the circulation. Besides this, we have other effects produced by this agent which are also good, such as a dehydration of the tissues; increased metabolism; increased activity of skin and kidneys; and an increase in the number of red blood cells.

The administration of the infusion intravenously is not a difficult procedure; all that is really essential is a fountain syringe, small pocket case, and a small cannula for syringe. A medicine dropper, in an emergency, answers the purpose very nicely. The arm below the shoulder should be constricted so as to make the superficial veins stand out; the vein chosen is usually the basilic or cephalic, just above the elbow. After thoroughly cleansing the overlying skin, cutting down on the vein and thoroughly isolating it from the surrounding connective tissue, a double ligature is passed underneath for the purpose of securing the vein below and above the point of opening. The vein is now opened in its longitudinal axis, the lower ligature being at once tied just below the incision into the vein; the tip of the cannula is next introduced (after first evacuating all air from tube), and the fluid allowed to flow slowly in. The time required should be about half an hour or longer. The amount used will vary with the conditions; when there has not been much loss of blood two or three pints will likely suffice; if, however, there has been much hemorrhage, more will be needed, five or six pints, or possibly more. The radial pulse is a good guide; when this grows full and strong, we have an indication that there is a beginning return to the normal condition. The temperature of the fluid is a question about which there has been some dispute. Bloodgood of Hopkins states that it should be 100° F.; Dawbarn of New York holds that it should be 120° F. The one is, I believe, too low, the other too high. A temperature of 108 ° F. or 110° F. is probably about correct. In giving it with the apparatus above described there will be a loss of two or three degrees of heat in the passage of the fluid through the tube into the veins, and the resulting temperature will not be productive of any harm. After the necessary amount has been introduced, the upper ligature should be securely tied and the wound dressed with a simple sterile dressing.

The slight rigor and elevation of temperature that often follows the use of this agent is transient and seldom proves alarming.

Having, then, by these means, brought about reaction, our next step is to act, and to act promptly; nothing is to be gained by temporizing.

For example, suppose the injury be done an extremity, if there be mangling of the tissues and crushing of the bones, as there often is, then removal of the limb is the only procedure. But not infrequently we meet with cases in which the injury sustained is a compound fracture or dislocation, with considerable damaging of the soft structures; and the question of amputation is often a very difficult one to decide. Here experience and judgment count for much, and not infrequently does the life of the patient hang upon the course pursued at this time.

In railroad surgery it should never be forgotten that the damage done the adjacent soft structures is often much greater and more extensive than we might suspect, owing either to the extreme violence of a momentary acting force as in head-end and rear-end collisions, or to the continued action of the initial violence, as in the dragging of brakemen and switchmen caught under the wheels. In my own experience I can recall one or two instances where an attempt was made to save the limb and death followed. Whereas, had the limb been removed promptly, I believe that the chances of life would have been enhanced. One especially is instructive.

The patient was a man, about forty years of age; head-end collision. At time of collision the patient was in the water-closet. The violence of the blow sent him forcibly forward, injuring both knees. The injury to the left was a compound fracture of femur just above the knee-joint, with much damage to the soft structures, the popliteal vessels not being severed. The shock was profound, taking about twelve hours to react. After reaction was established the patient was anæsthetized, the wound was enlarged and cleansed; the ends of the bone were trimmed up and adjusted and an attempt was made to save the limb. As stated before, the popliteal vessels did not seem to be seriously damaged, and for this reason especially the effort was made to retain the limb. The patient reacted fairly well from the operation, but did not improve, and it was soon manifest that the limb would have to be removed. This was done, but the patient never reacted from the second operation, dying in about five or six hours afterward.

In this case I believe that, had the limb been removed primarily, the chances for life would have been greater. There is no question that, if the damage done a limb, and especially if the injury be above the knee-joint in accidents to the lower extremity—be so severe that restoration cannot take place—then the sooner the limb be removed, the greater are the chances for recovery. For a limb in this state is a serious menace to life and unquestionably serves to perpetuate the condition of shock.

As to the point to be chosen for amputation in these cases no rigid rules should be laid down. Each case should be handled on its own merits, remembering, however, always to give the laboring man all the tissue possible, especially, if it be the hand, for here, truly, "every little bit helps." In all amputations through the foot we should ever bear in mind that the function of the foot is that of *support:* and to successfully obtain this we should have a plantar flap with a dorsal cicatrix; for this alone will give a stump sufficiently strong to support the body without pain and without ulcerations. Chas. Truax, in his "Mechanics of Surgery," makes this statement: "Avoid amputation within three inches of the ankle-joint. Do not amputate between the metatarsal bones and the junction of the lower and middle thirds of the tibia. At all other points save all you can, and you will, in every case, have done the best for your patient." This is, I think, a little radical and sweeping, for by its observance we will have to discard all the old classical amputations of Lisfranc—through the tarsometatarsal articulation of Chopart—through the mediotarsal joint; of Symes—through the tibiotarsal, and of Pirigoff—a modification of the last named. Certain it is that in most railway accidents done the foot, where the injury encroaches near the ankle-joint, there is usually so much damage done the plantar surface that amputation through the lower third of leg is the most rational procedure. When the injury is done the leg between the ankle and three inches below knee-joint, then we should go sufficiently high to get flaps that will insure primary union; for here a non-cicatrized stump is of more value in after life than an additional inch or so of leg would be. When the injury encroaches upon the knee we should endeavor to save everything possible, for whether the peg-leg or an artificial limb be subsequently used, the integrity of this joint, with even a small leverage, will be found most useful.

Above the knee the same general rules apply. It is especially in these thigh injuries that we often find ourselves forced to advance considerably higher than the injured point for a healthy flap, owing to the much larger amount of soft structures here involved.

In injuries done the upper extremity, if it be the hand or any part of the hand, save everything you can, making palmar flaps whenever practicable, because the nerve supply to the palm is greater and more highly educated than is that to the dorsal aspect. An artificial hand is, relatively speaking, of far less value than an artificial foot.

Between the wrist and elbow or between the elbow and shoulder, sacrifice if need be a little tissue to insure a good stump.

In conclusion, I would emphasize the following points:

The importance of an understanding and appreciation of the nervous phenomena of shock.

The value of the saline infusion, intravenously administered, for the relief of this condition in its graver forms.

The importance of prompt surgical interference immediately upon the establishment of reaction.

The importance of a plantar flap where the foot is involved or a palmar flap where the hand is involved. Never uselessly sacrifice tissue; never sacrifice a joint; and ever strive to leave your patient with a smooth, painless, non-contracted, non-cicatrized stump.

A FURTHER CONTRIBUTION TO OUR KNOWLEDGE OF ELECTRIC OZONATION AS A REMEDIAL AGENT, ESPECIALLY IN THE TREATMENT OF TUBERCULOSIS.*

By G. LENOX CURTIS, M.D.,
NEW YORK.

MEMBER AMERICAN AND NEW YORK STATE MEDICAL ASSOCIATIONS; MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK; HARLEM MEDICAL ASSOCIATION; CONSULTANT TO THE RED CROSS HOSPITAL.

THE scientific student of current medical affairs is apt to look upon recent progress in the therapy of tuberculous affections as merely the result of a natural process. He regards it as only one phase of the evolution of medicine, which, as we all know, is rapidly rising to a higher plane than even we of this electric age can picture in fancy's wildest color scheme. True, we are now beginning to appreciate the value of rational therapeutic methods, and to realize that drugs alone will not cure this intractable, insidious, and pernicious morbid process, by whatever name it be known. From a time beyond which the memory of man runneth not, the beneficent influences of sunlight and the atmosphere of elevated regions have been recognized in the treatment of tuberculosis. In fact, these are about the only measures that have positively availed much. Hence the time-honored injunction, "Go to a dry and sunny climate," founded upon empiricism rather than scientific observation perhaps, though I have not the least doubt that this advice is given with the sincerest motive in the large majority of cases.

It is now commonly understood that the air of a dry and sunny region is rich in that most active form of oxygen—ozone—upon which life depends. Who of us has failed to notice the peculiar odor that pervades the atmosphere after an electric storm? Who has not experienced the stimulating or bracing effect of the clear, pure air, after a midsummer display of Nature's artillery? Scientists state that the peculiar odor so apparent at that time is due to the presence of nascent ozone, the result of the electric discharges, and that it clears and purifies the air. Is it unreasonable to suppose that electricity is ozone?

---

* Read before the American Congress of Tuberculosis.

The fact that ozone is such a powerful oxidizing agent suggests the propriety of utilizing this property in the treatment of disease. If it be possible, as we know it is, to generate ozone electrically and force it into the body, is it not possible that the cause of a pathologic process may be destroyed—oxidized—and a normal, physiologic state reëstablished? I believe it is possible to attain just such results, and I believe that this is the key to the successful treatment of tuberculous affections, as I shall endeavor to demonstrate from my own experiences.

In my previous paper, which was published in the *New York Medical Journal* for January 18 and February 1, 1902, I explained the *modus operandi* of the generation and administration of nascent ozone. By this method ozone is forced into the body, taken up by the circulation and carried to the tissues wherein pathologic processes may be at work. There its effects are manifested in the arrest of the morbid operation and restoration of the structure and function of the affected organ. This apparatus produces a current which is sufficiently powerful to break up the molecular arrangement of the oxygen of the atmosphere, with the formation of ozone. The machine is essentially a system of coils, which multiply the voltage, the current being taken directly from the street main, to which connection is made by an ordinary plug. The capacity of the apparatus is 1,000,000 volts, at from one-fifth to one-sixth of an ampere, according to the intensity desired. To the machine is attached a single wire, which leads to a Geissler vacuum-tube and an ozone generator. This generator consists of a single loop of wire or of a brush made of many fine wires. Off its points and through the tube the electric fluid forms a fine spray, producing ozone, colored light, and heat.

Owing to the low amperage, there is no shock or unpleasant sensation in the use of this apparatus, such as is common in the comparatively low-voltage machines. To facilitate its use, a cabinet has been constructed high enough to permit a man to stand comfortably, and long enough to allow him to lie down, its area being kept purposely small, so that it can be heated at a small expenditure of electric current, and that its atmosphere can be quickly and readily permeated with ozone. It is fitted with a glass slab on a suitable table, and with four clusters of eight sixteen-candle-power lamps, two of which clusters are placed above and two below the slab, each fitted with a reflector and shade, which can be moved up and down, so as to secure varying degrees of heat in accordance with the requirements of the treatment; also with attachments for electrodes, a push button connected to a buzzer on the outside, and the ozone generator. Reflectors are placed around the sides of the cabinet, made of glass, which, together with the clusters of lamps mentioned, insure every portion of the exposed body being subjected to the effects of light rays.

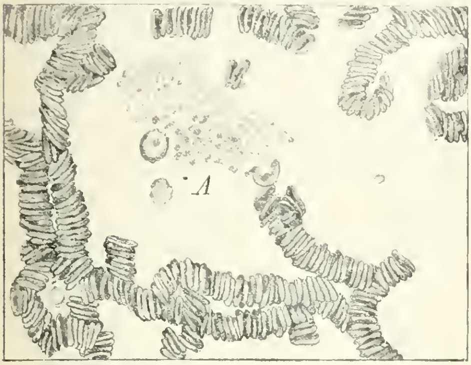
During the course of the treatment the atmosphere of the cabinet is permeated with nascent ozone, as before stated, which the patient inhales, while exposed to the heat and to the light rays, these rays resembling very closely in therapeutic value those from the sun. At the same time he grasps the electrode through which the current is passing, and, in a few moments, is thrown into a profuse perspiration. It has been found necessary for the patient to remain in the cabinet from twenty to thirty minutes to obtain the best results. After treatment he is subjected to a shower-bath for its cleansing effect upon the skin; then he is massaged with the electrode over the region where the disease is seated, to stimulate the muscular, cutaneous, or visceral circulation, and thus favorably influence the nutrition of the parts operated upon.

Ozone is carried into the body by inhalation and forced into localized areas by the Geissler vacuum-tube and generator, thus ozonizing all the tissues beneath the chosen locality. When the electrode is passed over normal regions no special sensation is experienced; but when a congested or inflamed area is reached pain is instantly felt, varying in degree according to the severity and extent of the inflammatory process. From the above statement, the diagnostic value of the electrode in locating internal inflammations may be understood readily. When a severe pain is developed a lighter current is used, or the electrode is frequently withdrawn. With these precautions it is found that as improvement takes place the full current can be applied with little or no discomfort.

In 1895 Molassez and Murphy described the effect of opening the abdomen and admitting air in the treatment of tuberculous peritonitis. It seemed that the air in some way checked the tubercular process. Watkins states that tuberculous matter, a product of the tubercular process, can be seen in the freshly-drawn blood of persons suffering from tuberculosis, but that it disappears after exposure of the blood to the air for a few minutes. I have observed this tuberculous matter in the blood of all cases of phthisis that I have treated by electric ozonation, and I have watched its gradual disappearance under the oxidizing influence of the agent employed. The same effect follows the employment of electric ozonation in lupus and other superficial forms of tuberculosis.

To my mind the idea that consolidation of the lung in pulmonary tuberculosis is always preceded by a pneumonic process is not yet clear. The pulmonary vesicles may become obstructed or filled with mucus, and their usefulness may become impaired, not as the result of a true pneumonia or inflammation, but rather as a consequence of impairment of normal function. The next step is the hardening of the vesicular contents, and in this way solidification of an entire lobule or lobe may ensue. From this viewpoint it is easy to explain how such tuberculous matter may be oxidized and dissolved, and the air cells cleared for the use for which they were designed by Nature. From two to six weeks' treatment is required to accomplish such a result; yet a local congestion may remain, so that the exudation is liable to recur until, under a continued course of electric ozonation, the structure is restored to a healthy state.

One great advantage in the use of this method is its dual action. While the local conditions are yielding to the gentle though aggressive effects of ozone, the general condition of the patient is made to feel its subtle influence, in the restoration of nerve-force, and improvement of the circulation and nutrition. In the course of two to four months the patient is usually so much improved as to warrant a most favorable prognosis. The general distressing symptoms abate from almost the very beginning of the course of treatment: the temperature and pulse rate fall, breathing becomes less rapid and labored, the appetite improves and sleep is more natural. After the areas of pulmonary induration begin to clear up, daily microscopic examinations of the sputum reveal a gradual reduction in the number of bacilli tuberculosis, streptococci and staphylococci, the latter disappearing first.



It is interesting to note how quickly nutrition is reëstablished under this mode of treatment. Foods and medicines, which formerly could not be tolerated, are now digested and assimilated, and utilized in the rebuilding of the depleted system. Of course every effort should be made in the management of these cases to reestablish the normal functions. To this end not only medicinal agents, such as iron, ammonium carbonate, strychnine, and laxatives should be employed, but also any indicated remedies should be judiciously prescribed *pro re nata*. Exercises designed to develop the physical powers should not be neglected, especially those that improve the capacity for breathing deeply and strengthen the voluntary muscular apparatus. In fact, I advise the employment of any rational means to aid the patient to recover his health.

Allowing that tuberculous matter is of an alkaline reaction, I have found that in order to facilitate its disintegration and absorption there is an advantage in endeavoring to "acidulate" the system, as it were, by means of acid drinks and inhalations. It is doubtless true that the effect of electric ozonation is to modify the alkalinity of the *materies morbi* and break down alkaline deposits; yet I have found that the mucopurulent nummuli are softened and expectorated with greater facility after the use of an acid inhalation. When the lung tissue has broken down the separation and discharge of the necrotic material is hastened by the same treatment. I have seen as much as a pint of débris discharged during a paroxysm of coughing, with great benefit to the patient. The acid treatment is applicable also to tubercular disease of the digestive tract, especially in advanced cases.

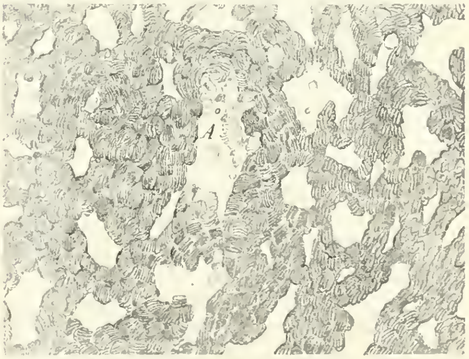
I believe the time has come when we shall have to admit that incipient tuberculosis is discernible only by an examination of the patient's blood, and that when the so-called first stage of the disease is recognized by the ordinary methods of physical diagnosis, the morbid process is already well established. Tuberculous matter, as observed under the microscope, appears granular, and sometimes as a cloudy mass resembling mucous. It is found in the serum, and sometimes is associated with the tubercle bacilli, and broken-down blood-cells, as shown at "A" in these photographs. An examination of freshly-drawn blood enables the expert to make an early diagnosis, long before the disease can be recognized by physical signs alone Advantage being taken of this fact, I am fully persuaded that the progress of the disease can be checked at this stage in almost every instance, when the habits of the patient can be controlled.

In addition to the measures referred to, it is important to institute a thorough method of disinfection of the rooms in which the patient lives, his wearing apparel, and his bedding. The pillows, especially, should be sterilized daily. When ozone cannot be utilized for that purpose, fumigation with formaldehyde is advisable. The mouth and nares should be douched daily with sterilizing agents, such as a solution of electrozone or hydrogen dioxide. Daily douching of the stomach and bowels with the same solutions would also be of service.

When the symptoms of tubercular disease are so conspicuous as to mask all other disease signs, the physician should be on his guard, lest complications be entirely overlooked. For instance, nasal catarrh should not be neglected. The same remark applies to rheumatism, malaria, and syphilis. The digestive functions must be carefully safeguarded, and the vital forces must be sustained. A reasonable amount of exercise is better for the patient than any form of the "rest-cure."

As a general result of my experience in the treatment of morbid processes by this method, I may state that resolution is hastened very markedly. Its beneficial effect upon the blood is most convincing, and is shown by an increase in the number of red discs, with a corresponding increase in the percentage of hæmoglobin and a diminution in number of the white corpuscles and destruction of pathogenic bacteria. The treatments are usually given daily until satisfactory results have been obtained, which, in a large percentage of cases, will ensue in a month.

In my former paper I reported a number of cases of various chronic diseases in which electric ozonation had been employed with definite results. At present I am giving particular attention to its effects in tubercular cases, and I hope to offer, ere long, a more tangible statement of the results of my observations in this class of cases.



A Gift of Two and a Half Million Dollars to London Hospitals.—Lord Strathcona and Mount Royal of Montreal has presented property worth half a million pounds to King Edward's Hospital Fund, formerly the "Prince of Wales' Hospital Fund," which was established several years ago for the purpose of extending financial aid to the hospitals of London, and which has prospered greatly through the labors and the influence of its royal patron.

TWO UNUSUAL COMPLICATIONS FOLLOWING CATARACT EXTRACTION: (1) DEATH AFTER CATARACT EXTRACTION FROM DIABETES; (2) DELIRIUM TREMENS FOLLOWING EXTRACTION OF CATARACT.*

By THOMAS R. POOLEY, M.D.,
NEW YORK.

The occurrence of complications other than those which are directly due to the surgical procedure after cataract extraction has received very little consideration, although all the possible phases of reaction dependent upon the latter cause have been described *ad infinitum* and almost *ad nauseam*. It is this consideration which determined me to report the following two cases:

Case I.—The patient, a woman sixty years old, was operated upon for cataract of the right eye on December 4, 1901, in the New Amsterdam Eye and Ear Hospital, by my colleague, Dr. George A. Taylor. The following brief history is entered upon the hospital records:

Eight months ago she first noticed failing sight in her right eye, which gradually became worse, until she was only able to discern light from darkness; she had had diabetes for years, and previous to the operation was for a considerable time under the treatment of Dr. Warner, and at the time of her coming to the hospital her urine showed an abundance of sugar. Before the operation was undertaken she was put upon a strictly anti-diabetic regimen and treatment under the care of her physician, Dr. Warner. At the time of her admission for operation there was a mature cataract of the right eye, mostly cortical in structure, with very little nuclear opacity. Perception of light and visual field excellent. The left eye showed an immature cataract of the same character, with vision reduced to counting fingers at a few feet. She was exceedingly anxious to be operated upon and gladly accepted any additional risk which might ensue from her diseased condition.

The operation, which was made under cocaine with the most complete regard to asepsis, was completed without the slightest mishap; iridectomy was made, the latter procedure being determined upon beforehand as giving the best chances of success. After the operation the lips of the wound were in apposition, there was still some cortical matter left in the anterior chamber which was not interfered with. The eye was thoroughly flushed with sterilized solution of boracic acid and the patient put to bed.

December 5.—Slight injection of conjunctiva, no pain, no infection, no prolapse of iris, shallow chamber, and wound not closed.

December 6.—Conjunctiva less injected, the cornea clear, no pain, counts fingers readily, a little incoherent and drowsy. She was given ten grains of trional and fifteen grains of citrate of potassium.

December 7.—Drowsiness more marked. Diagnosis, diabetic coma, not profound. Carbonate of lithium and codeine were administered.

December 8.—Eye clear, still counts fingers; wound not yet closed, no injection, appetite poor, nausea, and remains in a comatose condition until aroused. She is now taking milk, two ounces every four hours, codeine and arsenate of sodium combined with carbonate of lithium; this she takes with her milk.

December 9.—No appetite; restless. Passes enormous quantities of urine. Sat up during the night and bumped her eye against the bed-post; hemorrhage into the anterior chamber took place; the wound is partly closed.

December 10.—Hemorrhage in the anterior chamber is absorbing; the diabetic condition is worse; the wound is entirely closed, but there is slight conjunctival injection. Continued treatment as above. Coma more pronounced. Patient apparently dying.

December 11.—Died at 1.30 A.M.

Case II.—J. L., aged sixty-five, admitted to the hospital March 4, 1902, with mature cataracts in both eyes. Cataracts were of the usual senile type with large nuclei; perception of light and the visual field were good. The patient, however, was evidently a chronic drunkard. His wife, who accompanied him, gave the following history: For a number of years he drank to excess; suffers from alcoholic gastritis, but that he had had delirium tremens several times was carefully concealed and did not come to light until after the operation. Before his admission to the hospital, the patient had been seen by me at my office and was as thoroughly well prepared for the operation as was possible under the circumstances.

The operation was made under cocain and to my surprise uninterrupted by any excessive show of nervousness on the part of the patient. Simple extraction was accomplished without the slightest accident and with the least possible trauma. After the extraction of the cataract the lips of the wound came into perfect apposition; there was no prolapse of the iris, the anterior chamber rapidly refilled, and the iris was rapidly replaced to its normal position. Both eyes were bandaged and the patient was put to bed Just before the operation the patient took one pint of whiskey.

March 5; 3 P.M.—Bandage was removed; there was little injection of the eye. No prolapse. Perfectly round black pupil, but the patient had now become excessively nervous, although he had been allowed whiskey at short intervals ever since the operation. At 10 P.M. he began to talk incoherently and later became slightly delirious. He was given liquid diet and whiskey.

March 6; 3.30 P.M.—Bandage removed, counts fingers; iris in good condition; lips of wound in apposition. At 5 P.M. the patient was rapidly developing delirium tremens. He was given 30 grains of bromide of sodium, 10 grains of hydrate of chloral every three hours which quieted him during the night.

March 7.—The patient is now excessively violent and it is almost impossible to keep his bandage on. It became necessary to have a nurse by his bedside constantly. He was given 20 grains of bromide every two hours and a hypodermic injection of $\frac{1}{50}$ of a grain of hyoscine at 8 P.M. At 10 P.M. $\frac{1}{50}$ of a grain of hyoscine and one-half grain of morphine were given hypodermically and the bromides were stopped. He then slept from one o'clock to 8 A.M.

March 7.—Very delirious. Tympanites, suppression of urine, bowels have not moved since the operation and he has now prolapse of the iris and the wound is open. He still, however, counts fingers readily during the moments of abatement of his delirium. At 10 P.M. he received one-fourth grain of morphine, $\frac{1}{50}$ grain of hyoscine. Four ounces of milk with two ounces of whiskey were given every hour and a half.

March 8.—Delirium still worse. Pulse weak. Patient is only restrained now by a man nurse who sits at his bedside day and night. The bowels move freely; there is prolapse of the iris, with infiltration of the wound; the temperature is normal, pulse 92 respiration 24. Strychnine $\frac{1}{60}$ of a grain every four hours two ounces of milk and whiskey every two hours, hyoscine $\frac{1}{100}$ of a grain every four hours. Infiltration of the wound is worse.

---

*Read before the American Ophthalmological Society, July 16, 1902.

March 9 and 10.—Delirium continued with hardly any intervals of relief, and on the 10th there was more infiltration of the wound and the anterior chamber was filled with pus. At this time he was given apomorphine with better effect in relieving the delirium.

March 11.—The wound was gaping, there was prolapse of the iris, and anterior chamber was filled with pus. The condition now, so far as the eye was concerned, seeming hopeless, the patient was sent to his home for treatment by his family physician.

These two cases are extremely suggestive and interesting from several points of view. In the first place, the occurrences which immediately followed the operations illustrate what I think, no doubt, has occurred in the experience of all that any pre-existing disease or abnormal condition, although it may have been improved or held in abeyance by treatment, is very likely to be aggravated by any surgical procedure.

In the first case although the patient undoubtedly suffered from diabetes at the time of the operation, still her condition was not such as to warrant us in the belief that the operation was unjustifiable, or would have resulted, as it did, in a fatal issue.

As has been remarked in the history of the case, the patient was very carefully prepared by the treatment of an excellent physician before the ordeal of the operation, and notwithstanding, the occurrence of diabetic coma made its appearance within less than forty-eight hours after the operation, and rapidly progressed to a fatal termination.

This is the first occurrence of the kind which has ever come under my notice, although I have not hesitated to operate upon diabetic cataracts, always observing, however, the precaution to have the patient placed under proper treatment preliminary to operation, and frequent examinations of the urine made.

One case in particular, which I operated upon at intervals of about two years, was that of a man of seventy-two years, who had been suffering for a number of years with diabetes, and I obtained a very satisfactory result in both eyes, healing occurring without any complication whatever, and visual acuity also being satisfactory. In this case the patient was immediately put upon the usual anti-diabetic regimen for a number of weeks before the operation and during the healing process, so that, as the outcome of my own experience, I shall still continue to operate upon these subjects.

In the second case, it seems to me that the occurrence of a severe attack of delirium tremens, such as supervened after the operation, is even more dangerous to the integrity of the eye than in the preceding one, because of the almost impossible solution of the problem how to keep the patient quiet and prevent injury to the eye, which is almost sure to ensue. Although the patient and his wife freely admitted that he drank to excess for many years, and the nervous tremor which he showed at the time of his consultation with me were sufficient evidences of chronic alcoholism, still, with that fatuity so often shown by patients in their dealings with us, it was carefully concealed from me that he had had delirium tremens, which, if I had known, might have led me to reject the operation, or, at all events, to have made more careful preparation beforehand to secure the patient from injuring himself. As it was, had I only the usual resources of the hospital to depend upon. If I were to operate again upon such a case, I should feel inclined to restrain the patient by the use of straps, a straight-jacket, or even a plaster-of-paris jacket, until the wound had healed.

It is somewhat remarkable that there should have been so little reaction and such favorable closure of the wound at first, and that it was not until the violent efforts of the patient had resulted in a traumatic opening of it that subsequent infection gave rise to the loss of the eye. It seems to me, too, in this connection, that I had taken the precaution to make an iridectomy this might possibly have been averted.

Some recent German writer, whose name I do not now recall, remarks that the only way to treat such a case after operation is to let him take his whiskey bottle to bed with him. This in effect I really did, for it will be observed that virtually he was given all the whiskey he desired. That this, however, and the heroic treatment to which he was subjected after consultation with my colleagues had very little effect upon the course of the delirium, is obvious enough, and there is only one drug, viz., apomorphine, which seemed to have a decided effect in relieving the delirium.

107 Madison Avenue.

SANITARY PROTECTION FOR RURAL DISTRICTS.

By HARVEY B. BASHORE, M.D.,
WEST FAIRVIEW, PA.

As every one knows, the rural districts in this country are very inadequately protected by sanitary legislation. The cities, for the most part, are girt with sanitary laws which isolate them somewhat like the walled cities of medieval days, but this sanitary wall is a greater snare and delusion than the stone walls of our ancestors. Modern civilization, with its increased modes of travel, bring the country and the city into most intimate connection, and isolation is no longer possible. If the city expects to be safe, the whole country must be protected, for danger often lurks beyond the city's borders. Where is the boasted municipal protection if a person can travel from a suburban home where diphtheria rages to a crowded city? Where is safety if a smallpox patient can be buried with a public funeral just outside the city limits? Yet such things have happened and are happening to-day in many places in this country. Let me quote a few examples: Twelve patients with smallpox walking around in the country several miles from a town of 5,000 inhabitants; one death and a public funeral; the father of the dead child telling all this to the health board of the neighboring town, which, with the aid of the State Inspector, was investigating the cause of this outbreak of smallpox. This man claimed that no one told him he had smallpox, although the marks of the disease were indelibly stamped on his face.

Yet another story: Eighteen cases of diphtheria within one mile of a city of 50,000 people—closely connected by trolley and with intimate business relations—yet no legal restraint put on those people. Still that city is spending a good deal of money for sanitary protection.

England long ago found out the value of rural sanitation, and rural England, consequently all England has better sanitary protection than, probably, any other country. To learn all this England had to travel over a rough road strewn with the wrecks of mistaken ideas. Why should we tread the same hard path? Better begin with England's knowledge as it is to-day.

As the conditions are at present in this country each State makes its own laws, and, as a consequence, there is no general uniformity. The incorporated places—the cities and towns—take care of themselves, and they do it fairly well; but the administration in the outlying districts is varied and inadequate. Some States have county boards, some township boards, and some none at all. To be more exact, something like thirteen States have township boards and about twenty have county boards; this difference being probably due to the fact that in some States the county and in others the township is the political unit. Then, again, there are two States, Pennsylvania and Florida, which have neither county nor township boards—the state itself acting through agents in each county.

Although these States having a local board make a fairly good showing on paper, it is far different when it comes to actual practice, and no wonder, for of the thirteen township boards eleven are *ex-officio*, and of the twenty county boards eight are *ex-officio*. An *ex-officio* board of any kind is not generally of much value; it is the politicians' method of shifting work when the people are unwilling to pay taxes.

As over half of our States have these kind of boards, it simply means that over half of the country do not understand the advisability of paying out sufficient money for sanitary protection.

If one looks over the reports of these various local boards he can see in most instances lack of care—in many cases no report at all is given. It means that the right men are not selected because there is not sufficient renumeration and dignity attached to it to warrant the right man taking it. We may talk about patriotism—men have fought and died for their country and homes, and will do it again, but it is not right to ask them to serve the State for glory alone, in times of peace.

In England the county health officers, like our State officers, are trained sanitarians who are interested in the work and take pride in it, and they get just about twice the pay that the corresponding man gets in this country. Then there are health officers for each district (corresponding to our counties), every one a trained sanitarian and in the work for life; this local officer tramps, or bicycles, or drives, over his district again and again, and, in the course of years, gets to know every sanitary defect in it. He may advise, probably he does much of it, but back of his advice is the law. Such a system as this can only be potent for good.

Only three of our own States have a single county health officer, and one of them, Connecticut, has the peculiarity of having a lawyer for the county officer. How such an anomaly crept into Connecticut one can hardly conceive, for no one doubts but that the health protector of fifty or a hundred thousand people should be a sanitarian, and I have yet to hear of any lawyer who has had special training in sanitary matters. Of course, this system may do very well for administrative work, but it certainly will not promote the growth of sanitary science.

A single county health officer—which is, I think, the ideal method—should, of course, be a sanitarian—the more so the better; he should be appointed by the State Board of Health and be compelled to report to them, so as to centralize the authority; his appointment might be ratified by the local court. This ideal county health officer should have behind him the sanitary code and laws of the State, and it should be his duty to enforce them.

The township health officer might also be a physician or sanitarian, but I believe a very effective service could be rendered by having a layman and having him act simply as a sanitary policeman under the county officer to whom he would be responsible for his acts. He should placard, report nuisances, serve notices, etc. You will say that this is all very nice, but the cost! What of that? By taking a physician in active practice for county health officer (and many will be found capable), one may be procured in almost any place in the country for something like $400 or $500 per year, for when once organized the system would take very little time from his practice—the telephone and trolley facilitating matters in most counties.

A township health officer or policeman can be procured for something like $120 per year. Suppose there are ten townships in the county, this would make $1,200, and adding to this the salary of the county officer, the whole amount would hardly reach $2,000 per year—in some places more and in some, perhaps, less. Now suppose this county has taxable real estate to the value of $20,000,000, which is certainly a fair average in the Eastern and Central States; to furnish this meagre sum—to have efficient health protection—would cost only an additional tax rate of $0.0001—1-10 of a mill: this means ten cents per year for the man who owns a thousand-dollar house or one dollar per year for the man who owns a ten-thousand-dollar farm—surely any community can afford to pay this.

HYDROTHERAPEUTICS IN GASTROINTESTINAL DISEASES.*

By GEORGE MANNHEIMER, M.D.,

ATTENDING PHYSICIAN TO MT. SINAI DISPENSARY.

THE most important and valuable hydrotherapeutic procedures in gastrointestinal diseases are lavage and douching of the stomach and of the lower bowel.

We wash out the stomach in all cases where the onward movement of the gastric contents is interfered with owing to stenosis of the pylorus or the duodenum, with consecutive stagnation and fermentation, and in cases of intestinal obstruction. We furthermore practise lavage when there are accumulations of foreign substances in the gastric contents; for instance, mucus, as in chronic gastritis, pus from breaking-down neoplasms, superacid and superabundant gastric juices, as in gastrosuccorrhœa.

Nowadays intragastric hydrotherapy is used much more extensively; thus in the treatment of various gastric neuroses, motor and sensory. In cases of simple atony, a few washings of the stomach sometimes suffice to restore normal conditions, care being taken to avoid overdistension of the stomach and to evacuate all the water that has been introduced.

In gastralgia, douching of the organ with hot water may prove efficient. In nervous anorexia, nervous anacidity and subacidity, douching of the fasting stomach with water at 60° to 75° can restore normal secretions and the desire for food. Sodium chloride or infusions of bitter tonics are generally added to the water, in order to enhance its action.

The chemical and physical effects of such drugs as bicarbonate of soda, Emser or Carlsbad salt, bismuth or silver-nitrate, are utilized in many of the conditions mentioned, by adding them to the water.

The rationale of intragastric hydrotherapy is easily understood in cases of ischochymia, where its action is purely mechanical. In cases of ileus, evacuation of the gastric contents, and the consequent relief of tension, create a kind of syphonage from the intestines toward the stomach, thereby relieving intestinal tension and affording conditions favorable to the overcoming of the obstacle. These washings have to be repeated frequently at intervals of two to three hours.

---

*Read before the Metropolitan Medical Society, April, 1902.

In functional disorders water of higher temperature acts as a sedative, cold water as a stimulant, to the motor and secretory functions.

The psychical and moral effect of intragastric hydrotherapy certainly plays some part in bringing about the good results in some of these latter cases. Still, I want to emphasize that intragastric hydrotherapy in that group of cases commonly called gastrointestinal neurasthenia or nervous dyspepsia is very apt to prove a complete failure. This is preeminently the domain for the external application of water, which I will discuss later on.

In catarrhal jaundice, lavage of the stomach not only serves to relieve the distressing gastric symptoms, but may also help to dislodge, in a mechanical way, the plug of mucus occluding the common duct.

Dr. Ziemssen of Wiesbaden recommended gastric lavage with Wiesbadener Kochbrunnen (practically corresponding to normal salt-solution) as a cure for habitual constipation. From one to two pints are allowed to run in and out by alternately raising and lowering the funnel. This procedure excites active intestinal peristalsis, and, if practised daily for several weeks, may accomplish permanent results.

The introduction of water into the lower bowel is one of the most popular therapeutic measures. It is performed in various ways, and is easily modified according to the end in view. We may thus use small or large quantities of water, at varying temperatures, in short or long intervals, under high or low pressure, in various positions of the patient. and with various additions, such as salt, soap, glycerin, or oil. The commonest indication is coprostasis, acute or chronic. Here the injection softens the fæces, thereby facilitating their expulsion, and excites the peristalsis of the lower bowel. The best and simplest form of an evacuating enema for an adult is the injection of about a pint of water at 80° to 95°, with the addition of a little soap, administered from a fountain syringe in the recumbent position, and retained as long as possible. These injections may be used over long periods of time without doing harm.

The presence of oxyuris vermicularis, or other parasites, calls for mechanical cleansing of the colon.

All diseases of the large intestine are amenable to local treatment by means of water, but chiefly chronic cholitis with diarrhœa and mucus in the stools. Irrigations, with or without antiseptic or astringent admixtures, are here the most effective therapeutic procedures; likewise in ulcerations of the rectum and colon.

The best non-operative measures in chronic stenosis of the colon, in intussusceptions, in strangulated hernia, are high enemata of large quantities of water, or smaller quantities, with the addition of 5 to 8 per cent. sodium chloride, frequently repeated under low pressure, in the knee-chest or Trendelenburg position, eventually under anæsthesia. These measures may prove successful by removing fecal impactions, by facilitating the return of an intussusception, the untwisting of a volvulus, or the liberation of a strangulated loop. All these latter results, though difficult to explain in theory, have been observed in practice.

In the treatment of catarrhal icterus, irrigations of the colon have been recommended by Mosler and Krull. Mosler employs injections of a pint of lukewarm water three times daily, while Krull injects one to two quarts of water at 65°, and even lower once daily. The action of the former injections is eccoprotic, cleansing, diuretic, and indirectly cholagogue through increased absorption from the bowel, while the latter excite more energetic peristalsis of the colon and, perhaps, indirectly of the bile-ducts.

In enteralgia or intestinal colic, due to spastic constipation, lead poisoning, high copious enemata at 100° F., frequently repeated, are very serviceable.

The effect of prolonged flushings of the colon with hot saline solution by means of Kemp's tube on the general circulation, on the skin and kidneys, is well known.

To supply the system with water, we use the rectal route in cases where the ingestion of water into the stomach is undesirable, as in gastrectasia, or in the beginning of an ulcus-cure.

The local effect of heat and cold on the rectum is utilized in the palliative treatment of hemorrhoids.

The benefits obtained from internal hydrotherapy, that is lavage of the stomach and bowel, in the acute gastroenterites of children, are striking.

Turning now to the external use of water, it must be stated that there are no special hydrotherapeutic procedures for gastrointestinal diseases. These furnish the principal indications for the local use of water in the form of compresses, other local applications, and hip-bath

Compresses require an exact technique and an exact understanding of their rationale. If we want to reduce temperature and combat cerebral symptoms, as in the acute gastroenteritis of children, we apply a compress around the entire trunk of several layers of linen, well wrung out in water at 60° F., and covered by dry linen or flannel, and wet it again every hour until the desired effect is obtained.

Stimulating compresses covering the entire trunk or only the abdomen are applied in the same way, but they remain on the body until warm, that is for about four to five hours, or until dry—for instance, over night. They are indicated in chronic inflammatory conditions within the abdominal cavity, in venous stasis of the abdominal organs, and they allay manifold unpleasant sensations that interfere with the comfort and sleep of patients suffering from organic and functional disorders of the stomach and intestines.

Hot poultices have an undoubted value in favoring the absorption of local peritonitic exudates, whether these originate from a diseased appendix, from an inflammation of the sigmoid flexure, from perigastritis, or whether they form in the neighborhood of intestinal neoplasms. Poultices play an important rôle in the classical treatment of gastric ulcer. A hot-water bag placed over the abdomen is one of the most popular and effective applications to soothe intestinal colic. The so-called Winternitz combination compress deserves special mention because it is not well known. It consists of a stimulating abdominal compress, enclosing a rubber or Leiter's coil, through which water at 110° F. or more circulates continually. It is to be worn for an hour or longer at a time. It is a very effectual remedy for gastralgia, enteralgia, attacks of singultus or ructus, and for obstinate vomiting.

Local applications of cold in the form of iced compresses, rubber coils through which ice water circulates, or the ice-bag, are widely used in the treatment of diffuse and circumscribed peritonitis, to control hemorrhage from stomach and bowels, and in excessive meteorism. It is extremely doubtful whether an ice-bag really checks internal bleeding, or acts as an antiphlogistic on the locus morbi in acute appendicitis (perhaps, excepting people with very thin abdominal walls), but it certainly allays pain, compels the patient to lie quietly on his back, possibly lessens tympanites, and possibly inhibits peristalsis when applied for over an hour.

Sitz-baths or hip-baths powerfully influence the innervation of the abdominal and pelvic organs and the capacity of the abdominal vessels, the largest blood reservoir of the body, the filling of which controls, to a great extent, the general circulation and blood pressure.

Cold or very hot hip-baths contract the abdominal vessels, driving the blood to other parts, as evidenced by congestion of the head, increase of axillary temperature, rise of the plethysmographic curve of the arm, and lowering of the rectal temperature. If this thermic irritation lasts but one to three minutes, prompt reaction ensues, that is active hyperæmia of the abdominal organs, but if it lasts ten minutes or more, prolonged ischæmia of that vast vascular area takes place, with weak and retarded reaction. Short cold hip-baths stimulate peristalsis, prolonged cold ones inhibit it, prolonged warm ones soothe pain and spasmodic contractions. Short cold hip-baths (50° to 65°) are therefore indicated in all conditions of the abdominal organs which are due to anæmia, venous stasis, motor and secretory insufficiency, torpid metabolism—for instance, in atonic constipation. Hip-baths at 50° to 68°, lasting ten to thirty minutes, according to Winternitz, act almost specifically in checking all forms of acute and chronic diarrhœa. They are, furthermore, indicated in bleeding and inflamed piles. Prolonged tepid hip-baths, at 70° to 80°, have a similar though milder action. Hip-baths at 90° to 100°, of one to two hours' duration, are suitable for colic and tenesmus.

All these local applications are very advantageously combined with general hydriatic procedures; thus the short cold hip-baths recommended in atonic constipation and flatulence are preferably followed by a douche of gradually-reduced temperature or a Scotch douche on the abdomen, and later by a stimulating douche to the entire surface. The prolonged cold sitz-baths are appropriately preceded by a drip-sheet and vigorous friction.

Hydrotherapy should be general whenever possible; that is, it should be applied to the entire surface of the body, because its best effects are brought out in that way; namely, its influence on circulation, respiration and innervation, over secretions and excretions.

General hydrotherapeutic procedures find their greatest field of usefulness in chronic disorders of the gastrointestinal tract, especially the functional ones, be the latter a manifestation of neurasthenia or hysteria, or the primary cause of the disturbance of the cerebrospinal centers. The constitutional tonic treatment, as carried out to greatest perfection at the Hydriatic Institute and the Riverside Baths, consists of graduated douches (circular, jet, and fan douche) of one to two minutes' duration, preceded by artificial warming of the body and followed by friction.

The following measures are appropriate for home treatment. Ablutions by means of a rough towel, a bath glove, or the hand with water at 80°, reduced one to two degrees each day down to 60°; affusions with water at the same temperature; the drip-sheet from 70° to 60°; the cold plunge; and the wet pack from 70° to 50°, followed by a half bath from 85° to 80°. We employ one or the other of these applications, according to whether symptoms of irritation or depression predominate in the particular case, and whether the patient is poorly or well-nourished, anæmic or plethoric. It is the great advantage of hydrotherapy that it can be so modified as to suit almost any case and condition where it is at all indicated.

In conclusion, I wish to say that I have achieved my best results in the management of gastrointestinal diseases by combining the hygienic, dietetic, and medicinal treatment with hydrotherapy.

1001 Madison Avenue.

The Artificial Sterilization of Women.—Hubl divides the procedures by which the occurrence of pregnancy can be avoided into two classes. The first of these, the castrating operations, involve the removal of either the uterus or ovaries or both, and the second, which he terms the sterilizing operations, effect the purpose without the loss of any essential portion of the genital apparatus. Castration in this sense and for the purpose of effecting artificial sterility is permissible only in those cases in which the removal of the uterus or adnexa is directly indicated for disease, or an already existing infection, or the necessity for cæsarean section demand a hysterectomy. If, however, the indications for a double oophorectomy exist, the uterus should also be taken. In many cases of osteomalacia it is expedient to interrupt the pregnancy at an early date, and in these it is advisable to perform a vaginal hysterectomy, and so avoid the danger of another pregnancy and possible laparotomy. In performing cæsarean section for osteomalacia, castration may usually be satisfactorily replaced by sterilization, and of the different methods advocated for this purpose the following is the most effective and suitable: The uterine attachments of the tubes are exposed and surrounded by several sutures of fine silk, the ends of which are left loose. The uterine end of the tube is then excised, together with a small wedge of the uterine muscle surrounding it, and the previously-inserted sutures are quickly tightened to prevent hemorrhage. The entire tube is then excised, both layers of the broad ligament are sutured, and finally the incisions in the uterus are carefully sutured. In the pregnant uterus the site of the tubal insertion is very vascular and troublesome oozing may take place unless precautions are taken to prevent it.—*Monatsschrift für Geburtshülfe und Gynäkologie.*

The Use of Carbonated Waters at Meals.—Alfred W. Perry says that the earliest perceptible sign of disorder of the stomach is a derangement of its motor function. Practically no water is absorbed from the stomach; it must all pass first into the intestines. It is well known that the amount of urine secreted in health is a measure of the absorption of water from the intestines, the blood pressure being unchanged from other causes. By experimentation the author found that the use of cold CO_2 water increased the diuresis 12 per cent. over plain water; when these were used during meals, with CO_2 water at 86°F., the diuresis, and presumably the stomach discharge, was increased nearly 100 per cent.. We may conclude that, although hot drinks at meals, or soon after, are generally best for most dyspeptics, for those who will not use hot drinks CO_2 water, cool or slightly warmed, have a very beneficial effect in causing a prompt discharge of the stomach contents.—*Pacific Medical Journal.*

The Pubescent and Adolescent Periods of Girlhood.—William Edward Fitch protests against overworking young girls physically and mentally at or about the age of puberty. Intricate dances, exhibitions, children's parties, and too-stimulating work at school are condemned on the one hand, and child labor in stores, factories, and sweat shops, on the other. "Medical tinkering," too, with young girls is to be avoided, and emmenagogues for irregular menstruation need seldom be used. The writer reports a case in point in which living in the open air and becoming interested in country surroundings and occupations, combined with the taking of peptomangan, resulted in the complete cure of a young girl whose menstruation had been irregular for more than a year.—*Annals of Gynecology and Pediatry.*

INFANTILE SUMMER DIARRHŒA IS DYSENTERY.

So many garbled and sensational reports have appeared in the daily newspapers in the past few days concerning an alleged discovery of the specific germ of the summer diarrhœa of infants that the MEDICAL RECORD felt called upon to send one of its staff to make a personal investigation, in order to separate the wheat from the chaff for the benefit of its readers. It is hardly necessary to say that no one connected with this interesting research is responsible for its unfortunate exploitation in the lay press. As in many similar instances, an over-zealous hospital patient and the enterprising reporters have caused the scientists no end of trouble and annoyance—so much so, indeed, in this case that the latter were disinclined to give out any information at this time. However, the following is a brief statement of what has been accomplished, and, although only the salient features are given, it may be relied on, for Professor William H. Welch has kindly read the account here given and vouches for its accuracy.

During the past summer Messrs. C. W. Duval and V. H. Bassett, fourth-year medical students—the former at the University of Pennsylvania and the latter at the Johns Hopkins University—engaged in an investigation of the causation of the summer diarrhœas of infants at the Thomas Wilson Sanitarium, near Baltimore. The work was undertaken with the aid of an appropriation, granted, for the purpose of this investigation, by the Rockefeller Institute of Medical Research. Mr. Duval had already, in collaboration with Mr. Vedder and under the supervision of Professor Flexner, engaged in a study of the acute dysentery of adults in this country, and thereby had become familiar with the characters and the methods of isolation of the bacillus which causes this disease, *Bacillus dysenteriæ*, Shiga. This previous work enabled him to discover, in the first two cases of summer diarrhœa of infants which he examined, the Shiga bacillus. In the further investigations Mr. Bassett was associated with him in the research. They have found the Shiga bacillus in the stools in over forty cases of infantile summer diarrhœa. It was present in large numbers in acute cases, but was obtained with difficulty from mild and chronic cases. They had no opportunity of examining the type of the disease, known in the restricted sense as cholera infantum, which constitutes, according to Dr. Holt, only 2 or 3 per cent of the cases of summer diarrhœa of infants.

The Shiga bacillus was not found in the stools of healthy infants or of those affected with other diseases, of whom many were examined as controls.

An important aid, in the diagnosis both of the disease and of the specific bacillus, is the agglutinating power of the blood of infants affected with the disease as regards the bacillus, as well as the agglutination produced by specific immune sera. The investigators believe that the evidence is sufficient to justify their conclusion that this bacillus is the cause of at least most cases of summer diarrhœa of infants, but, of course, it is desirable that similar observations should be made elsewhere and on a larger scale.

Doubtless the reasons why previous investigators have failed to detect the Shiga bacillus in this disease are partly the unusual difficulty in discovering specific germs in the extensive and varied intestinal flora, and partly that special familiarity with the modes of isolation and recognition of the Shiga bacillus is necessary for its detection.

It is hoped that the discovery of the specific infectious agent concerned in the causation of this most frightful scourge of infancy will lead to improved methods of prevention and cure. In his article on "Bacillary Dysentery," in the forthcoming supplementary volume of the Twentieth Century Practice, Shiga reports some excellent results in the treatment of this disease by means of a specific bactericidal serum, and there is every reason to hope the same method will prove to be equally efficacious in infantile dysentery. The Rockefeller Institute will continue work along these lines next summer.

TYPHOID FEVER IN RURAL DISTRICTS.

IN the natural course of events the autumn will bring the usual increase of typhoid fever cases in the large cities. When it is conceded that the majority, if not all the victims of attack, are those who have spent their vacations in rural districts, there is a penalty on rest and recreation which is becoming difficult to avert. In fact, it would appear, considering the number of causative factors at work in the ordinary farm-house, resorts that the possibility of stamping out the disease at its sources is a long way off. The alluring promises of rural advantages are in themselves threats of danger.

The farmer who is ambitious to eke out his scanty income by taking summer boarders is by no means a practical sanitarian. It is difficult to persuade him that the moss-covered bucket of his forbears, his sunken well, and his convenient privy vault are not in keeping with the otherwise healthfulness of his surroundings and in fulfilment of all the æsthetic requirements of his improvised hotel plant. While he may not be blamed for his ignorance of hygiene, he is plainly accountable for assuming the responsibility of enforcing his convictions upon his trustful and unsuspecting patrons.

Thus it is that many must suffer and continue to do so until health boards can have the power to inspect and license all such places as are so freely advertised to the public as health resorts, and which are now proven to be so dangerous to the ordinary wayfarer. If this were done there would be a certain guarantee to the boarder that while striving to gain health and strength he would not be jeopardizing his life by exposure to a hidden and waiting infection.

There is certainly no more reason why a person keeping a public house should not have a health license than the milk vendor, or the ordinary lodging-house keeper. If there should be a demand for such a clean bill of health, the conscientious farmer would be anxious on business principles to comply with it, knowing that a contrary course might seriously affect him pecuniarily.

The various health boards throughout the States have the power to insist upon such provisions, and have the necessary facilities for marking the localities in which, for instance, epidemics of typhoid have occurred; and of enforcing certain sanitary regulations tending to prevent the spread of the disease. This has been shown time and time again after a given epidemic has gained headway and a general panic has been created, but the truly practical aspect of the question is obviously more in the direction of prevention than in that of cure.

If the trouble were attacked at its source, the initiative cases watched and traced, and the proper sanitary regulations duly enforced, there would be no reason why every country district should not be purged of its pest. The first factor in the equation is the family physician, whose duty it should be to report every case of typhoid to his district health board, and trust to the latter to investigate the source of the infection, and not be satisfied until all chances of the further spread of the disease has passed.

It is not enough that no cases of fever prevail at the the time, but all the traces of previous ones must have been obliterated. There cannot be too much insistence on this point, as it is well known that the poison may lurk in a quiescent state for many months only to declare itself when fresh material is at hand for its propagation.

A well once infected can never be trusted, and a contaminated water supply left to itself may threaten new comers for a long time to come. Even the intervention of wintry weather with its snow and ice is no safeguard against the occurrence of new cases in the following spring and summer. The difficulty of being sure on this point lies at the bottom of most of the otherwise unaccountable causes of a fresh epidemic. For instance, an epidemic in Plymouth, Pa., was recrudescent when a thaw set free infective fecal matter which had been frozen for three months in the snow and ice on the border of a brook.

When we take into account the multifarious ways in which the typhoid poison may disseminate itself when it has once escaped from the human body, we have the strongest possible argument for rendering it inert from the start. While little can be done to prevent the walking cases of typhoid depositing the germ in all sorts of convenient places and thus infecting soil and water, the case is entirely different when the country practitioner is called early to attend a patient attacked in the ordinary way. Under such circumstances a careful physician, by proper sanitary precautions, which center in the careful disinfection of the typhoid stools, can as absolutely prevent the spread of the disease as by quenching fire with water. That he does not do so is plain enough in the multiplication of his cases afterward. No better proof of the utility of necessary precautions can be presented than that afforded by the thorough aseptic methods practised in our hospitals. When the careless rural practitioner appreciates this fact in all its widespread bearings, he will have taken his first and most essential step in attempting to stamp out constantly-recurring epidemics in his neighborhood.

THE DISTRIBUTION OF CANCER IN BERLIN.

There is a theory concerning the causation of cancer which is prevalent among a certain section of the medical profession, and especially so among a number of British physicians. This is, that a particular type of house, or the situation of the same, has a dominant influence on the origin of cancer; so much so, indeed, that such houses have been termed cancer-bcen houses. Investigations made by numerous observers into the matter have resulted in no definite proof as to the truth of the theory, although it would seem reasonable that locality and climatic conditions might have some effect on the progress of the disease.

Dr. Albert Aschoff has written recently on "verbreitung der Carcinoma in Berlin," the main features of his article having been translated into the *Middlesex Hospital Gazette.*

Observations made by Dr. Aschoff regarding the endemic nature of cancer on the Island of Nordeney were as follows: The town is divided into a high-lying northwest portion, built on the sandy soil of the old dunes, and a southeast portion, which is low-lying and built on chalk. Aschoff finds that in the former district cases of cancer are but rare, in the latter relatively much more frequent, and especially is this so in a part of the chalk district, which he calls the garden district. In this garden district the houses, although old, are apparently in sound condition, but it is stated that in this quarter there is always water standing in the cellars. The houses are situated in gardens, in which various vegetables and fruit are cultivated. Aschoff notes that although in these gardens the trees and plants are generally free from galls and tumors, there is a prevalence of mildew and rust on the rose trees. In the district there are many old families that have resided there for many years, but there has been little intermarrying.

In his account of the distribution of cancer in Berlin, Aschoff states that of 4,574 cases 2,736 occurred in women and 1,838 in men, but after deducting the cases of cancer of the female generative organs the male cases were in excess—1,838 males to 1,658 females.

Regarding the relative frequency of different seats of the disease, the digestive tract and accessory organs come first, accounting for 1,571 cases—833 in men and 738 in women—out of the total of 4,574, or 34.34 per cent. In considering the distribution amongst various occupations and trades, three divisions are made:

1. Those patients who are engaged in trade, of which twenty varieties or groups are taken into account.

2. Those belonging to the so-called "free call-

ings," comprising those of the various professions, officials, soldiers, and servants.

3. Those who have no special occupation, and of these there are six different groups.

On analyzing the deaths in each of the three divisions and assigning them to their respective groups, it is found that in division 1, out of 10,000 deaths 671 are from cancer, and that 33 per cent. of the patients are over forty years of age; in division 2, out of 10,000 deaths there are 720 from cancer, and 37 per cent. of the cases are over forty years of age; in division 3, out of 10,000 deaths there are 780 from cancer, 92 per cent. being over forty years of age.

Considering the frequency of the disease in certain groups included in these divisions, Aschoff finds that in division 1 the lowest number of cases occurred in printers, and that the death rate was low amongst chemical workers and machinists, but that the mortality was high amongst gardeners, and especially so amongst foresters and agriculturists. In division 2 the mortality was lowest amongst soldiers and servants, most of whom are, of course, young persons; it was low also amongst medical men, but high amongst public officials, professors and clergymen. In division 3 cancer is most frequent amongst the well-to-do "pensionäre" and old "rentiers," being more common amongst those than amongst the occupants of almshouses. No reliable evidence on the influence of the site of the dwelling-house was obtainable; in many cases no information was to be obtained on this point, and frequent change of residence further detracts from the value of any observation made.

Aschoff finds that there is a greater frequency of cancer in certain districts of Berlin, and may be noted even in special streets of such districts, and in special portions of the streets. But the distribution of the disease over the town is very irregular, and its significance difficult to explain. The density of the population is no criterion for the increase of cancer in any particular district, nor has the social status of the inhabitants any obvious influence, the richer and poorer quarters suffering alike.

In conclusion, Aschoff returns to the questions: Is cancer transferable from man to man? Does cancer occur more frequently in special districts? And he concludes that his investigations into the distribution of the disease in Berlin does not give any certain answer to either. But the comparatively low percentage of cancer cases amongst medical men and medical attendants, and also the fact that the percentage of cases is not greater in proportion to the density of population, or amongst the generally more crowded together classes.

As to the influence of soil, no definite statement can be made, high or low-lying damp districts and sandy or alluvial soils being variously affected, nor does the water supply afford any basis of explanation; whilst as to the influence of food supply, meal or vegetable diet, the use of raw or uncooked food, Aschoff cannot, from his observations, make any statement. On the whole, the deductions as to the cause of cancer made by Dr. Aschoff do not differ in many essential points from those reached by other investigators.

Haviland Hall, the chief supporter of the theory that the location and condition of a house are prominent factors in the causation of cancer, has a comparatively small following.

A large number of medical men will be found to disagree with Dr. Aschoff's assertion that cancer makes as much headway among the poorer classes as among the well-to-do. The view usually taken now is that cancer, for reasons not clearly explained, attacks the well-fed individual more often than his attenuated brother. Further than this, Roger Williams and others are of the opinion that meat-eating people are more prone to the disease than those who are addicted to a vegetable diet, which explains why cancer has increased so greatly within the past twenty or thirty years among the inhabitants of the United States, Great Britain, and Australia. At any rate the mass of statistics on the subject go to show that the poorer classes are less liable to cancer than the richer classes.

PUBLIC CHARITY AND POLITICS.

On the occasion of laying the corner-stone for the new hospital building at Dobb's Ferry, N. Y., Governor Odell gave his views on charity institutions, which are of much significance, coming, as they did, from a business man and a politician.

Among other things he said, "politics should never be permitted to be a factor in the administration of institutions for the unfortunate. It has no place there, and I have so much confidence in the wisdom of our people that I do not believe they would tolerate such interference and would be quick to condemn those who were instrumental in taking advantage of the deplorable physical conditions which exist in our institutions for either party or personal benefit."

These sentiments were well calculated to inspire an enthusiastic and unsophisticated country audience, and were thoroughly in accord with the spirit of the hour. No one present would have dared to believe that the speaker was misinformed concerning his facts, nor to doubt that he would not on all occasions do his best to prove the truth of his gloriously philanthropic doctrine.

Under the circumstances it was eminently proper for him to look on the bright side of the question, and to give proper encouragement to such of the trustees as seemed destined to make new rules for a very old game. Alas, for them, however; they will find too soon that politics in one way or another is as much a factor in hospital management by laymen as is the free and willing treatment of the sick by the medical servants of the institutions. None knows this better than the orator of the occasion, and none has done more to prove the opposite of what he would feign have the public believe.

We have only to refer to his Excellency's recent action in the matter of the Lunacy bill to prove that politics cannot always be divorced from the higher interests of caring for the sick and the helpless. At present there is no more powerful political machine in the country than that which controls the lunatic asylums of the State, and none in which the Chief Executive has taken a more active interest. The legislation against the State Charity Associations would be an apt illustration of like inconsistency on the part of the Governor, unless it could be proved that he was innocent of using his powerful influence in the wrong direction.

We are not to be understood as taking any issue with the Governor on his avowed principles as expressed in his address. On the contrary, his sentiments are of the noblest sort, and come, of course, from a man who believes what he says and dares to express his honest convictions. Politics in hospitals and state institutions! Certainly there must be no such thing when the poor and sick are concerned. It is only when a sufficient amount of surplus money can be saved to the public and some extra patronage utilized for party interests that politics, as such, should have anything to do with the direction of public charity. This was evidently meant but not said.

From such a point of view the little hospital at Dobb's Ferry, with its limited funds, its modest field of labor, and its small subscription list, is quite likely to be free from political control for a long time to come, and it was eminently safe to promise that what could not be should not be. But let its management be worth the while of any faction or sect, and willing souls will rise to bless the privilege and willing hands to utilize the opportunity.

Perhaps the Governor has gone too far in his zeal for the right. It may yet be a serious question how far politics can safely be dispensed with in the management of our charities. Without such disinterested control how could our funds be properly expended, our medical talent selected, merit rewarded, and the greatest good done to all? The apparent justice of the thing makes the strongest appeal to our own common sense. How otherwise could the large hospitals secure their staffs, the colleges their teachers, the health-boards their distinguished heads, and how, in the confusion of conflicting interests, could the right man always come to the front. If there be any doubts on this point, we have only to ask the men who occupy the places.

Overwork and Recreation.

A great deal has been said of late in connection with the alleged physical breakdown of a leading business man, regarding the value of recreation as an offset against overwork. There is, however, a side to the argument which is not always made apparent in the general eagerness to christen every form of debility as neurasthenia. Since the late Dr. George M. Beard invented the term and wrote intelligently and comprehensively on its bearings upon the habits and customs of the American people, it has been quite indiscriminately applied to almost every form of nervous disability, no matter how induced.

It is so complimentary to the individual affected to say that his zeal in his work overcame his strength that few victims care to deny the soft impeachment, and quite contentedly resign themselves to the pity and commiseration of their anxious friends. The physician knows very well, however, that much of this sympathy is wasted on undeserving subjects. It is not so much the abstract work that does the business as the culpable perversion of its aim and purposes. Rarely does real work in itself kill any one. In other words, the busiest of men can keep healthy and strong provided they abide by the simplest laws of his being. If between times he sleeps well, rests when tired and eats well, he is seldom, if ever, worn out before his time. Thus it follows that most of the cases of so-styled neurasthenia have their foundation in abuses of digestion and in habits of dissipation, while innocent work gets the blame.

In a recent interview to a daily newspaper an octogenarian who had been engaged in an active and exacting business all his life remarked that he had never found time nor inclination to take a vacation during that period. He simply took his rest by piecemeal and never needed it in bulk. His was the faculty of doing the best he could as he went along and bearing his successes and failures with equal equanimity. There was no need for strain, because no time was lost. The fret and spurt of modern business are more to blame than the steady jog, which latter always counts most in the end. The manner of doing the work is more than the work itself. Regarding this point there is much to be said against the growing disposition toward dissipation among business men. The tippling habit at luncheon, excessive smoking, late hours, midnight suppers, and similar excesses, explain more of the cases of neurasthenia among the so-styled overworked men than all other causes combined. Let us call things by their right names and pity those only who deserve it.

Hallucinations and Illusions.

Dr. George T. Tuttle, of McLean Hospital, Waverley, Mass., delivered an address on the above subject before the Middlesex South District Medical Society on April 17. After describing the various views taken as to the definition of hallucinations and illusions by different authors, Dr. Tuttle says: "An examination has been made of the clinical histories of 500 consecutive admissions of persons to the McLean Hospital—222 men and 278 women—excluding those not insane and readmissions; of these 189—77 men and 112 women—had hallucinations or illusions of some sort. This is 37.8 per cent. By far the larger part were of hearing only; next in frequency came sight and hearing; after that sight alone—these two, separately or combined, making 166 out of a total of 189 persons. A number of examples are then given of these different forms of illusions, and it is remarked that hallucinations and illusions of sight are less frequent than those of hearing, probably because comparatively few people visualize their thoughts. The author states that since 1881 he has been convinced that hallucinations may not only be of psychical origin, but may be voluntarily produced, and brings forward several instances in support of this conclusion.

It is noted that there is abundant evidence to show that hallucinations and illusions are by no means limited to the insane. The sensory disturbances of dreams, are examples of sense-perceptions, often most vivid—hallucinations when due purely to association of ideas, illusions when induced by stimulations of sensory nerves. Like all others, they are previously-received impressions variously modified, combined, and rearranged.

Closely allied to dreams are the hypnagogic illusions which occur just as one is dropping off to sleep—rapidly, shifting visions, supposed to be due to the seeing of vessels, pupil blood corpuscles, etc., from which, in the half-conscious condition, these pictures are formed.

The international censes of waking hallucinations, which was first undertaken by Mr. Edmund Gurney showed a percentage of 11.96 hallucinations in

27,329 presumably sane persons, 9.75 per cent. of which were in men, and 14.56 per cent. in women, and more than half occurred between the ages of fifteen and thirty years. In 48 per cent. of the cases no statement was made as to health. In about 44 per cent. the positive statement is made that the percipient was in good health at the time.

Referring to the so-called collective hallucinations, Dr. Tuttle states that the evidence which would be of value concerning such is slight, and he prefers to consider these phenomena of hallucinations or illusions as coincidences, but which occur in accordance with the laws of mind, and which cannot always be explained with our present knowledge.

The question of spiritualism is dismissed somewhat briefly, and that though it still survives the numbers of believers is not now increasing rapidly because of theosophy, Christian science, and other fads, which appeal to similar elements in human nature. In conclusion the writer sums up as follows: How are we to explain these perversions of sense? What underlying condition renders it possible for them to occur? How are they produced? Are we to suppose a supersensitiveness, or an over-excitation of the sensory centers, or a condition of lessened activity of the highest, the inhibitory-centers, or both combined. Certainly they do not occur at times of clear thought, but only when the higher cerebral functions are relaxed. Occupation of the attention in any way will cause them to cease, or will lessen their frequency. Various theories have been advanced to explain them, but in respect to no one is there a substantial agreement.

TREATMENT OF PARESIS.

The above subject was discussed in a paper read by Dr. Edward Cowles, Waverley, Mass., before the Medical Society of the State of New York, January 28. It is pointed out that, aside from all the generally indicated expedients for the management of cases of paresis, the real therapeutic problem of treatment is a most baffling one. Although pathological anatomy has determined, to some extent, the cause of the disease, nevertheless, the pathological anatomist leads but little further than the frontier of our realm. Dr. Cowles thinks that the explanation of our clinical problems lie in the still deeper underlying plane of physiological chemistry.

With regard to etiology, in accordance with the principles of general medicine, limitations in the logic of treatment are found under the leading conceptions of the etiological factors of paresis which are syphilis and heredity, with alcohol and the stress of modern life contributing. The experience at the McLean Hospital, Waverley, Mass., agrees with that of many observers in the evidence it gives that paresis is due less to heredity than other forms of insanity. The rôle of heredity, in whatever relation it may bear to insanity in general, is that of inducing a constitutional instability.

Dr. Cowles holds that the argument in favor of paresis having its chief cause in specific disease is not a conclusion from any discoverable relation between known specific and paretic lesions, and that Krafft-Ebing's dictum that general paralysis is a product of civilization and syphilization, and Oppenheim's statement that paresis is the outcome of stress and syphilis, give expression to opinions that indicate no more than a sequence of facts, showing the frequency with which specific infection is followed by paresis.

Dr. Cowles, after discussing the views recently expressed by prominent authorities on the matter, concludes that we still find ourselves in the region of hypothesis, with waiting expectations of new light upon the treatment of paresis, but with reasonable faith in their final realization.

DISEASE-BEARING DUST.

Some few weeks ago reference was made in the MEDICAL RECORD to the evil effects of dust, especially in large cities. The fact is now well recognized that dust is often distinctly injurious to health, as well as being a nuisance of the first order. The effectual suppression of dust is a problem, the solving of which is a matter of great moment to the inhabitants of all large centers of population. Watering streets is but a partial and temporary solution of the difficulty, and does not strike the root of the question. What is needed is a method whereby permanent relief will be afforded. Various means to effect this end have been suggested, none of which, however, has been both practicable and efficacious.

Cosmos, July 26, quotes from an article contributed by Dr. Guglieminetti of Monte Carlo to *La Salubrité*, Paris. In the course of the paper the following remarks are made:

"Watering is a good thing as far as it goes; but to fight dust successfully we must do so by means as constant as the causes that produce it. This would necessitate an expenditure for water that no city budget could reasonably stand. Besides, while the water lays the dust for the moment, it softens the road and allows the vehicles to cut into it more deeply, thereby preparing the elements of more abundant dust when the water shall have evaporated. Thus watering is really only a costly palliative, which combats the evil momentarily without attacking its causes. As is well known, petroleum has been used in the place of water with some degree of success, and on a somewhat large scale in various parts of America, but the method, though fairly successful, is by no means ideal."

Dr. Guglieminetti has invented a system, which he thus describes: "The road is first swept clean and then covered with a thin layer of hot tar, well spread out. This plan was tried at Monaco on March 13, 1902. After forty days' use the surface of the road did not appear to be injured. The dust did not stick to it, but will probably do so in the summer, as the tar will soften slightly."

Dr. Guglieminetti further says that experiments under his supervision are to be extended to Paris streets, and that tar, mineral oil, and various kinds of petroleum will be tried. Since the article in *La Salubrité* appeared, the trials there referred to have taken place with so much success that it has been decided to apply the petroleum method in Paris, Lyons, Nice, and Marseilles. Of course, it is probable, or rather certain, that the best mode of "laying the dust" has not yet been evolved, but the outlook for such an event is in a high degree hopeful. When rich municipalities show themselves willing to expend money to attain an object there can be little doubt that the time of fulfilment will not be far distant.

Acute Rheumatism.—Fussell directs attention to the value of the tincture of chloride of iron in acute rheumatism, large doses of ipecac in dysentery, bichloride of mercury, 1 gram to 1 ounce of lime water, in dermatitisvenenata, nitric acid as a local application to the osuteri, mercurial ointment in pruritus ani, and large doses of nitro-muriatic acid in functional inactivity of the liver.

News of the Week.

New Surgeon-General of the Army.—Brig.-Gen. William H. Forwood, Surgeon-General, U. S. A., was retired on September 6, on account of age, and was succeeded by Brig.-Gen. Robert M. O'Reilly, Gen. O'Reilly was until recently at the head of the Medical Corps of the Department of California, and has just returned to Washington from a sanitary inspection of the more important military posts between that city and San Francisco. He was official physician at the White House during the two terms of President Cleveland.

Medical Society of the State of New York.—The President of this Society has appointed Dr. Ernest Wende, 471 Delaware Avenue, Buffalo; Dr. Hamilton D. Wey, Elmira; and Dr. J. Montgomery Mosher, Albany, the Business Committee, to whom all communications relating to the program of the next annual meeting, January 27-29, 1903, in Albany, may be addressed.

Cholera in the Far East.—It is not only in the Philippines that cholera is working ravages this year, for the entire east coast of Asia and the outlying islands are suffering from the epidemic. According to reports brought by incoming steamers, the outbreak exceeds in the area covered and the number of victims any previous epidemic of which there is record. The disease prevails from Java to Japan, and almost every city on the coast and many in the interior are affected. The disease, too, is being contracted by Europeans as well as natives. In Hong Kong, from the first of the outbreak to August 6, there had been 523 cases, six being in Europeans, and 511 had died, of whom four were Europeans. In Tien-Tsin the last report placed the number of cases for the year at 1,049 and 764 deaths within the city walls, and 1,015 cases and 593 deaths outside the city walls. In other places in China the proportion of cases and deaths is just as great. Great numbers have died in Java, and Japan has suffered severely. In Borneo a military expedition, despatched to the interior to punish a tribe of natives for outrages committed against Europeans, was more than decimated by cholera and was forced to return with its mission unfulfilled. There has been no permanent improvement in the situation in Luzon. The army is protected by the enforcement of stringent sanitary regulations, especially in regard to the drinking water, but the Chinese and Tagalogs are suffering severely.

Typhoid Fever.—There has been a progressive increase in the number of reported cases of typhoid fever in Philadelphia each week since the end of July, until now the disease is fairly epidemic. The influence of the water supply on the prevalence of the disease is exemplified in the fact that while the rest of the city is suffering so severely there is little or no typhoid fever in Manayunk, which is now receiving filtered water from the lower Roxborough beds. In Chicago there is also a progressive increase, but here, while the water is bad enough, much of the infection appears to have been acquired from salads and other garden truck grown in fields which have been flooded with sewage containing typhoid dejecta.

The Association for the Protection of the Adirondacks has begun the agitation of a proposition to acquire more land within the Adirondack Park. The limits of this park were defined ten years ago, but as yet the State owns much less than half of the three million acres which the proposed park measures. The wisdom of acquiring title to the whole of this tract as soon as possible is manifest. Eventually this city will have to look to the Adirondack region for the greater part of its water supply, and then public control of the watershed will be an absolute necessity. But it is not the city alone that will benefit; it would be an even greater calamity to the State at large than to the city to have this great region denuded of its forests, its rainfall decreased, and its lakes dried up. The land will never be cheaper than it is now, and as its purchase will be for the good of posterity, there would be no injustice in incurring for this purpose a debt for posterity to discharge.

The International Conference on Improving the Condition of the Insane opened on Monday of last week at Antwerp, under the Presidency of M. van den Heuvel, the Belgian Minister of Justice. Those attending the conference included a representative of China, as well as delegates from most of the leading countries of Europe. The general opinion expressed at the Congress was that cottage settlements were preferable to asylums in the treatment of the insane. The following resolutions were passed before the Congress closed: (1) That the confinement of the insane henceforth be abandoned except in the cases of those recognized as dangerous. (2) That the system of boarding insane persons with families be carried out whenever possible. (3) That it is expedient to renew the wish formulated at the Congress at Paris for the establishment of schools for special classes of the mentally weak under medical supervision. (4) That the manner of placing patients be entirely left to physicians. (5) That forcible restraint should be condemned.

Gift to the Jersey City Hospital.—Mr. Cornelius Zabriskie has offered to give $150,000 toward building a new City Hospital in Jersey City, on condition that residents of the city shall raise a like amount by subscription. Mr. Zabriskie also makes it a condition that politics shall be kept out of the hospital management. Dr. John D. McGill of the Health Board has promised to give $25,000 toward the public subscription, and to do all that he can in aiding to collect the remaining $125,000. It is expected that Mayor Fagin will give the project his official sanction. The control of the hospital is now being contested by the health authorities and the politicians, and if Mr. Zabriskie's offer is accepted this unseemly quarrel will be stilled.

Opposition to Temperance Agitation in Germany.—The Berlin correspondent of the *New York Times* says that temperance agitation is evidently considered a serious offense by German officialdom. Dr. Mabli of Danzig, an army surgeon of high rank and head of a Good Templar order, who was for many years active on behalf of temperance, recently received an order to stop speaking publicly on that question. He consequently resigned his post in the army. A similar case happened at Guben, whence a Royal Railroad Director named DeTorra was transferred to another place because it was alleged that temperance agitation was incompatible with his official duties.

Trouble in a Newark Hospital.—An investigation is about to be made in Newark of certain charges brought by a Catholic priest against the members of the house staff of the City Hospital. The priest charges that he has repeatedly been interfered with when attempting to administer the last sacraments of the Church to patients in the hospitals, and also that on several occasions he has detected certain members of the medical house staff eavesdropping behind screens while he was hearing the confessions of patients. The charges have aroused considerable indignation, and are to be the subject of investigation not only by the Medical Board of the Hospital but also by the Board of Health and the City officials.

A Physician Sued for One Dollar.—A physician in Yonkers is defendant in a suit brought by a carriage-maker to recover $1, which the plaintiff claims is due for repairs to the defendant's wagon. The physician says that he never had any work done by the plaintiff, and the lawyers will get many times the amount in dispute before the question of fact is judicially settled.

"Adobe Itch" is the name popularly given to one of the effections which has caused great annoyance to our troops in the Philippines, but which has been practically eradicated by very simple precautionary measures. The effection is similar to, if not identical with, the "water itch," a disease of the feet of coolies working in the gardens of China, and is caused by a species of Acarus resembling that of scabies. An investigation of the trouble led the army surgeons in Manila to believe that it was communicated by the careless methods employed by the Chinese in doing laundry work. They were in the habit of drying the clothes by spreading them on bushes and on the grass, and ironing them with a cold iron. Under the belief that the parasite came from the vegetation, and was communicated to the clothes from the bushes, orders were issued that clothes would be hung on lines to dry, and ironed with hot irons instead of cold. As a result of this practice the disease disappeared.

Increase in the Length of Life.—The Census Bureau has issued a statement showing the increasing age of the population of this country from decade to decade. The statement, as quoted by a correspondent of the Associated Press, gives the results of computing the median instead of the average age. The median is such an age that half the population is under it and half is over it. The median age of the total population in 1900 was 22.8, as compared with 21.9 in 1890. The median age of the white population in the last census year was 23.4 and the colored, including negroes, Indians and Mongolians, was 19.7, while in 1890 the white population was 22.4 and the colored 18.3. The report shows there was an increase in the median age of the white population during each decade from 1810 to 1900 amounting in the ninety years to 7.4 years. The statement adds: "Many complex influences have co-operated in producing as a resultant this steady change in the age composition of the population. Three may be mentioned, the rapid progress of medical and sanitary science, which has tended to increase the average length of life; the decrease in the relative number of children born, which has made the earlier age periods less preponderant numerically in the total population and the influx, especially since 1840, of great numbers of adult immigrants, increasing the number in the older age periods."

Smallpox.—The first case of smallpox in this city since August 19, was reported to the Board of Health on Friday of last week, September 5. The patient was removed to North Brother Island, and the usual precautions in the way of disinfection and quarantine were taken by the health officers.

Cooper Medical College.—According to the terms of the will of the widow of Dr. Levi Cooper Lane, who died on August 9 (Dr. Lane died in February of this year), the bulk of the estate, appraised at over $300,000, will go to the Cooper Medical College of San Francisco.

Patent Insides in Medical Journalism.—We learn from some of our contemporaries that a proposition has been made to supply them each month with plates containing twenty-four pages of original articles, translations, and abstracts. These plates will be furnished in exchange for a certain number of pages of free advertising, the concern supplying the "literature" having full control over these pages to advertise anything it may please with any display it may think best.

A New Plan of Campaign Against Mosquitos.—The sanitary authorities in New Orleans have been working to reduce the number of mosquitos and succeeded in having introduced into the City Council an ordinance requiring householders to sprinkle their cisterns with oil or cover them with wire netting so as to keep out the mosquitos in breeding season. This has, however, been so urgently opposed by the householders on the ground that it would cost them some $400,000 and prove a great hardship for the poorer people that the Council has held it up. Now one of the members of the Council has come forward with a substitute plan for exterminating the mosquitos in the city by introducing a fungus disease among them that will cause their death. He argues that the infection of mosquitos with a disease that will kill them off will cost much less and that the city can provide for the experiments instead of unloading the burden on the property holders. It would be well, however, for this ingenious and economical member to know something about the disease he proposes to propagate, and whether the germ is really fatal to mosquitos and to them only, or like that of malaria and of yellow fever, simply tarries with them a while while getting itself into shape for the infection of human beings. The plan of extermination proposed by the health authorities is simple and efficacious, as Major Georges has shown in Havana, and it could just as well be carried out at the expense of the city as the dangerous alternative proposed by the councillor.

Religious Mania Epidemic among Russian Immigrants.—Much apprehension is felt in Canada as to the fate during the coming winter of the Doukhobortsi, a sect of Russian dissenters who have been settling in large numbers in the Canadian northwest. The mania has assumed a vegetarian form. Those affected, of whom there are said to be five thousand, have discarded the use of horses and cattle, and have let them run wild on the prairie. They will not eat the flesh of any animal, and live on bread, water, and a few vegetables. A few weeks ago the worst among them decided not to wear leather shoes or woollen clothing, since these are of animal origin. It is feared that the suffering will be appalling when winter sets in, if the mania does not abate, or the Government does not act soon in some way.

Obituary Notes.—Dr. St. George W. Teackle of Baltimore died in that city on August 30. He was a graduate of the University of Maryland School of Medicine in 1870.

Dr. Reuben Morris Sutphen of Newark, N. J. died in the home of his son, Dr. T. Y. Sutphen, at Short Hills, N. J., on September 2, at the age of eighty-three years. He was born near Princeton, N. J., on April 25, 1819, but received his early education at Ontario, N. Y. Deciding to take up medicine as his life work, he entered the office of Dr. Voyht of Freehold, later attending the Medical Department of the University of New York, from which institution he was graduated in 1847. He practiced in Walworth, Wayne County, N. Y., before settling in Newark in 1868. He was a member of the Newark Medical Association, the Essex County District Medical Society, and the New Jersey State Medical Society.

Dr. Mortimer V. Wilkie died at his home at Cuddebackville, near Port Jervis, N. Y., on August

31, at the age of forty-five years. He was born in Buffalo, and educated at Holbrook's Military Academy at Sing Sing. Later he was graduated from the medical department of Columbia University in 1888, and for the next five years was connected with the Manhattan Hospital, New York City. A widow and two children survive him.

Dr. Frank Seabourne died at Bordentown, N. J., on August 17 at the age of thirty-three years. He was a graduate of the Medico-Chirurgical College of Philadelphia.

Dr. George A. Bodamer died at Philadelphia on August 20, after a protracted illness at the age of forty-three years. He was graduated from the Medical Department of the University of Pennsylvania in 1884.

Dr. Michael Bradley, Medical Director of the United States Navy, retired, died at Philadelphia, after a protracted illness, on August 27, at the age of sixty-five years. He became an assistant surgeon in the Navy at the beginning of the Civil War and in 1861 was ordered to the gunboat Louisiana, of the North Atlantic Squadron, being present at the capture of Roanoke Island, rendering active service in many important engagements. After the war Dr. Bradley was attached to the South Pacific and European stations. For two years he was surgeon at the Norfolk Navy Yard. In 1879 he was commissioned Medical Inspector. He was stationed at League Island from 1882 to 1886. In 1888 he was made Medical Inspector with special duty in Philadelphia and in 1895 he was retired.

Dr. George S. Hull formerly of Chambersburg, Pa., died at Pasadena, Cal., on August 29, at the age of fifty years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1876.

Dr. Claudius B. Webster, who was the oldest living alumnus of Dartmouth College, died at Concord, N. H., September 7, aged 86 years. He was graduated from Dartmouth in 1837. He studied medicine with a brother at Boscawen, attending lectures at the Dartmouth Medical College. He later studied at the College of Physicians and Surgeons in New York, where he obtained his degree in 1844. He practised for a time and then took the principalship of the Norwich (Conn.) Female Acaddemy, where he remained for eighteen years. In 1862 he visited Washington, D. C., and as a result of that visit gave up his school work and became Assistant Surgeon in the United States Army. He remained at his post until after the close of the war. In 1870 he was appointed United States Consul to Sheffield, England, by President Grant, where he remained for sixteen years.

Etiology of Pneumococcus Peritonitis.—F. de Quervain, upon the basis of two cases reported by him and all the others which have been hitherto recorded, gives the following etiological subdivisions of pneumococcus peritonitis: (1) Aclinically secondary form. Here the source of the infection may be (*a*) upper-air passages, one case reported; (*b*) lungs and pleura, fourteen cases reported, eight in children and six in adults; (*c*) the intestinal tract from ulcerated new growths or other chronic ulcerative processes, four cases reported all in adults; from traumatic injuries, three cases reported; from the appendix, eighteen cases reported, seventeen in adults and one in a child; following pneumococcus enteritis, two cases reported; (*d*) the female genital tract, one case reported originating in the tubes. (2) A clinically primary form; forty cases reported, twenty-nine in adults, eleven in children.—*Correspondenz-Blatt für Schweizer Aerzte.*

Obituary.

RUDOLF VIRCHOW.

BERLIN.

Professor Rudolf Virchow died at his home in Berlin on Friday, September 5, as a result of a fracture of the neck of the femur received in a fall from a street car in January of this year. The fracture never healed and some time ago it became evident to his sorrowing friends that the career of this great scientist, statesman, philanthropist, and lovable old man was nearing its end. He spent the summer away from Berlin in Bohemia, and later in the Harz Mountains, but, knowing that his end was near, he sought his home to die, and was carried back to Berlin on the last Sunday of his life. Even then, in the shadow of the great journey where one must walk alone, his interest in his fellows and in his beloved science was not dimmed, and only three days before his end he accepted the honorary presidency of the newly-founded German Society for the Exploration of Anatolia, in order to give to the work his sanction and the support of his name. Virchow was an honorary citizen of Berlin, and the municipality accorded to his remains a public funeral, which took place on Tuesday of this week, the procession starting from the Rathshaus. The eulogies were pronounced by the Burgomeister of Berlin, Herr Kirschner, and Prof. Waldeyer of the University.

Virchow was the son of a small shopkeeper and farmer in the Pomeranian village of Schivelbein, where he was born on October 13, 1821. Until he was thirteen years old he attended the *Volkschule* of his native town, from which he passed to the *Gymnasium* at Köslin. Four years later, at the age of seventeen, he began the study of medicine at the University of Berlin, where, after a five-year course, he received his medical degree in 1843, and was at once appointed assistant physician at the Charité. During his course at the University, his circumstances were very straitened and he was forced to enroll himself in the *Pepiniere*, along with Helmholtz, among those who, in return for free instruction, bound themselves to serve the State for a definite period after graduation. In 1846, when but twenty-five years old, he became head of the Charité, succeeding Froriep, and the following year was made an extraordinary professor at the University of Berlin. He had previously, in collaboration with Benno Reichhardt, founded his *Archiv*, the full title of which is *Archiv für pathologische Anatomie und Physiologie und klinische Medicin.*

Young Virchow first came prominently before the public in 1848. At that time he was appointed junior member of a government commission to investigate the epidemic of typhus fever among the starving inhabitants of the Silesian highlands. His report, embodying the result of his studies, was regarded as brilliant and profound. It gave direction immediately both to his scientific bent as a student of pathology and to his political career, for in this report the fearless young savant did not hesitate to attribute the ravages of the disease to the maladministration of the province or to lay many sins of omission at the door of his Majesty of Prussia. The investigation thus introduced him to politics, and laid the foundation for the brilliant parliamentary career in which he always championed the cause of the people. But the radical views which he held and freely expressed during those revolutionary times caused his expulsion, in 1849, from his chair at the Berlin University. He immediately received an offer of a Professorship in the University of Würzburg, which he accepted, and it was there that he did some of his most remarkable work. He remained for seven years in Würzburg, during which he began his most celebrated work, "Cellular Pathology," published in 1858, which has made his name immortal in the annals of science and medicine. There he began the "Hand-book of Special Pathology and Therapeutics," which helped to insure his renown, and he instituted his "Annual Reports of Advances in Medicine throughout the World." Before Virchow went there, the University of Würzburg was held in slight esteem, but through his work, and that of other brilliant young men inspired by his example, it was raised to the front rank of medical schools.

But Virchow was too great a man to be kept in the comparative obscurity of a small university town. The Prussian Government established the Pathological Institute in 1856, and could do nothing else than place this already famous man at its head. He was accordingly recalled to Berlin, being made at the same time full or ordinary professor of pathology at the University. In 1857 he published his first work upon anthropology, a science which he may be said to have founded. It was "Investigations upon the Development of the Cranium." He founded, too, the Society of Anthropology, and long acted as its president. He established standard measurements for comparative anthropology, and set officials to work in all the countries of Europe measuring the heads of school children and adults, collecting statistics concerning the color of their hair and eyes, and tabulating other race data.

Although as early as 1849 a sufferer for his political faith, it was not until ten years later that his activity in statecraft began. In 1859 he was elected by the Liberals as member of the Municipal Council of Berlin. He entered the House of Deputies in 1862, retiring from the Liberal leadership in 1878, which he made over to Eugene Richter, and was a member of the Reichstag form 1880 to 1893. He was the originator of the term *Kulturkampf*, to designate the war of the State against the Church. In his political career he was far from exhibiting the calm of the scientist or the bonhomie of the man of the world, for his convictions were too fierce to allow him to be anything but a hard hitter. Here the violence of his political opinions and constant watchfulness against the seeming encroachments on liberty and attempts to obtain further power by the throne were his chief characteristics. In 1863 he carried an address which arraigned the Prussian Ministry as violators of the Constitution, and in June, 1865, he aided in defeating the Government in its attempt to create a navy. In the debate on the subject his language was so bitter that Count Bismarck challenged him to a duel, which, however, never came off.

But the list of this wonderful man's activities is not yet complete. No man of his century could with better right apply to himself the words of Terence: *Homo sum; humani nihil a me alienum puto.* His interests in humanity were simply without limit, and one thing led him on to another until he had embraced, either in actual work or intelligent appreciation, the entire round of human activity. His authropological studies led him to delve into archæology, and he became a firm friend and supporter of Schliemann. It is said, indeed, that the discoveries at Troy were due almost as much to Virchow's suggestions and enthusiastic encouragement as to the courage and labors of Schliemann himself, and, at the latter's death, Curtius said there was but one man living who was fit to carry on and complete his work, that man being Virchow.

In all this time, however, there was no rest from his labors in the advancement of medical science, and scarcely a year passed during nearly half a century that some important contribution from him was not published. He had the open mind of the true scientist and never rejected any theory that seemed to conflict with his own until he had satisfied himself by actual proof and weighing of facts that it was unworthy of acceptance. He was slow to accept the doctrine of the microparasitic theory of disease, not because it endangered the doctrine of cellular pathology, of which he was the father, but because he was not satisfied of its truth. When he was finally convinced that bacteria play a large part in the production of morbid action, he accepted the new doctrine, and modified his own teachings to accord with it.

A catalogue of the scientific bodies which have from time to time honored themselves by electing Professor Virchow to honorary membership cannot be given, for it includes practically every society of prominence in the civilized world. The celebration of his eightieth birthday, not quite a year ago, is fresh in the minds of all. At that time he was the recipient of more eulogy than perhaps has ever fallen to the lot of man to hear, but while affording the simple old man a very natural gratification, it left him just as simple and just as lovable as before. To an American delegation present at the home celebration in Berlin he said, with a twinkle in his eye, that they need not take the journey to help him celebrate his ninetieth birthday, for he had it in mind to take a little vacation then and would come over to America.

This is but a bare outline sketch of the life of the greatest scientist of the nineteenth century. A fuller appreciation of his work and of its far-reaching influence on medical thought must await another occasion.

The Employment of Digitalis and Aconite in the Treatment of Cardiac Disease.—H. A. Hare is convinced that in the great majority of cases digitalis is given in doses which are much too large, and often continued over a period which is far too long. He has often been surprised by the excellent results produced by the use of such small amounts as one or two minims of an active, physiologically-tested tincture of digitalis given three or four times a day, the patient being, of course, required to rest, and so to give his heart that most-needed therapeutic aid when its compensation is ruptured. In many cases no cardiac stimulant is needed, but aconite will be of value from its steadying effect on the heart through the action of the vagi, its sedative influence on the heart muscle in cases of excessive compensation, and its relaxing effect on the blood vessels, diminishing the overaction of hypertrophy, which is sometimes confused with the tumultuous overaction of ruptured compensation. Sometimes the use of well-balanced doses of aconite and digitalis have produced results which neither could produce by itself, although, at first glance, they are physiological antagonists.—*The Therapeutic Gazette.*

A Rare Symptom in Peripheral Facial Paralysis.—R. Cassirer reports six cases of facial paralysis in which the symptom known as Hitzig's phenomenon was observed. It consists in a mechanical irritability of the paralyzed muscles, in that when they are thus irritated a powerful contraction of considerable duration is produced. The individual facial muscles on either side may in this manner be made to contract, and a temporary picture of unilateral facial paralysis thus produced. No such contractions can be produced by irritations other than mechanical, except by the galvanic current. The causation of this phenomenon is unknown, and but little attention has been paid to it since it was originally described by Erb and Hitzig in 1876. It cannot be produced in other forms of peripheral paralysis.—*Centralblatt fur Nervenheilkunde und Psychiatrie.*

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HEALTH—TUBERCULOSIS AND NOTIFICATION—CANCER NOTES—RELIGIO MEDICI SCIENTIFIC—A PATHOLOGICAL SCHOLARSHIP—FLIES AND TYPHOID.

LONDON, August 22, 1902.

AFTER a week of great activity, the King started yesterday on a cruise to Scotland, and will call at several ports on the way. Sir Frederic Treves has taken leave of his Majesty after eight weeks' attendance. These facts should put to shame the gutter press, which has persisted in circulating false statements about the King's health, though his medical advisers have given most formal assurances of his complete recovery.

The war against tuberculosis is being waged with great zeal, especially by sanitarians. General practitioners often attribute to medical officers of health more zeal than discretion. However this may be in individual cases, the general sanitary service of the country must be credited with an earnest endeavor to prevent what they say is a preventable disease, and to educate the public on the preventive measures necessary. As to these, the optimistic view is scarcely adopted by clinical observers, and the public is reluctant to admit some of the restrictions urged.

At Manchester the public health section had a discussion on the subject, in which the advocates of notification were in the ascendant. But they had to admit that it would be of no value without supplementary measures, while their opponents pointed out the objection of patients to be labeled contagious, which would lead to more or less ostracism. This objection has since been sadly illustrated by a poor woman who had murdered her child because, as it was suffering from eczema, other children were forbidden to play with it. Verily, the notificationists will have much educational work to do among the poor and ignorant before their remedy will be tolerated. Dr. Ransome told medical officers of health that their chief duty was to improve the conditions of life of the poor, especially of their dwellings, which plan he called the English as distinguished from notification, the continental method. On the other hand, Dr. Robertson "wanted, in the first instance," four special enactments; a demand which looks almost like crying for the moon. Dr. Newsholme said everyone now admits the desirability of voluntary notification, a plan adopted at Manchester with a certain degree of success as well as at Brighton and some other towns.

In reference to this, Dr. Beatty gave an account of the measures adopted in Manchester, which follow the notification. These seem reasonable enough so far, but how much further they should be pushed is open to question. As to *compulsory* notification, there is not the least prospect of Parliament entertaining it. If it could be carried out, it would be useless without the most extensive and costly supplementary measures. The optimists, who think Parliament will enforce their views, are doomed to disappointment. There is one point which these advocates of compulsion seem to ignore. They dilate on its proved value in smallpox. But how different is the case of a chronic disease of the slight infectiousness of phthisis, and that easily controlled, from that of an acute, virulent infectious disease like smallpox or diphtheria. In these the issue is soon determined, in that the danger, though slight, is prolonged. Nevertheless, yesterday Sir Charles Cameron, in his Presidential address to the Institute of Public Health, made a strong appeal for compulsory notification, declaring it to be absolutely necessary for the prevention of phthisis. He said the proper thing was to obtain an act enabling sanitary authorities to enforce compulsion. It is not likely Parliament will pass such a measure.

Cancer research and questions relating to cancer are still prominent The pathological department of the cancer hospital, Brompton, has been reorganized, and an additional laboratory for research is being equipped. Mr. H. G. Plimmer, who has hitherto acted as pathologist to the hospital, is to be the director, and another gentleman will be appointed to act under him as pathologist. The cancer research fund of the two colleges progresses.

The Duke of Bedford has promised £1,000 per annum for three years to the fund.

The Middlesex Hospital fund is also progressing.

Mr. Jonathon Hutchinson's notion that the increase of cancer is caused by the increased dissemination of arsenic in modern civilized life, is not finding much acceptance. Arsenic has been blamed for peripheral neuritis, for beriberi, and other diseases, and the suggestion that cancer may be set up by it seems almost a reflection of the popular terror provoked by the arsenical beer epidemic. Nevertheless, Mr. Hutchinson seems to hold fast to his idea, judging from the polyclinic, in which he reiterates it. Dr. Solomon Smith draws attention to chimney-sweeps' cancer, and the acknowledged influence of soot in provoking it, and Dr. Shadwell remarks that one of the keys of cancer causation lies in the case of chimney-sweeps, though that key has not yet been found. The suggestion is that, whether taken in food or medicine, or applied externally or inhaled as dust, arsenic predisposes the tissues to take on cancerous action. If so, one would have supposed that dermatologists would have noticed it, for a section of them have used the poison most extensively. Moreover, it has been freely given as a remedy for some forms of malignant disease.

A book of 216 pages has just appeared under the rather unattractive title "Religio Medici, Religio Scientiæ, Religio Vitæ," by a student of science and medicine, 1849-1899. After the title page there is no more Latin, and one may regret that some simple English should not have been chosen to designate a book which might be read with advantage by many who may be repulsed by the pedantic title. The student, as you may gather from the work itself, is a Fellow of the Royal Society and of the Royal College of Physicians, who has been actively engaged as a teacher at one of our schools of medicine for some fifty years.

I will respect the rather transparent veil of his anonymity, though you will probably penetrate it at once when I tell you that the distinction between protoplasm and bioplasm bulks largely in what he has to say. He naturally objects to the way in which Haeckel and Spencer employ the word "organic" as synonymous with "living." Any student of chemistry or materia-medica would tell them that the word is constantly applied to dead matter. Haeckel may talk of "carbon as creator" and Verworn may predict the "laboratory production of living matter," but they would laugh to scorn the assertion that any man had really produced a living thing by synthesis. Haeckel hailed Huxley's "Bathybius," and said "the greatest theologian of the nineteenth century was led by this wonderful discovery to abandon his outworn Christian view." Spencer declares in his "Principles of Biology" that "crystals grow." Equally absurd assertions may be gathered from agnostic writers who pose as scientific authorities, but whose juggling with words plainly shows their lack of the scientific mind.

A scholarship of £200, to extend over two or three years, if the work done at first promise well, has been offered by Mr. Mason of Woodstock. This work is to investigate the physiology and pathology of the thymus, and may include research on other ductless glands. Drs. Caverhill of Edinburgh, and Professor Woodhead, with the founder will select a candidate, giving preference to one who has already been engaged in similar work and will devote his whole time to the proposed research.

At the annual meeting of the Association of Sanitary Inspectors, Sir J. Crichton-Browne gave a useful address on flies as disease mongers. He told his audienec that experience in South Africa strengthened the suspicion that these insects disseminated typhoid fever. He followed up this and other equally suggestive facts by enforcing the practical lesson as to getting rid of dust heaps and dirt of all sorts from the proximity of dwellings, and especially urged the preservation of milk and all food from the access of flies. An excellent lesson for housekeepers and cooks, as well as for the sanitary inspectors.

OUR PARIS LETTER.

(From Our Special Correspondent.)

INCREASE OF MALIGNANT CASES OF DIPHTHERIA IN PARIS—DENTAL SURGERY EXAMINATIONS IN PARIS—CASE OF TYPHOID PERFORATION—SERUM OF TRUNECEK—CAUSES OF DEATH IN DIPHTHERIA—NEW BOOK BY DR. BROCA.

PARIS, August, 1902.

AT a recent meeting of the Medical Society of the Paris Hospitals, Dr. Marfan, a well-known specialist in pediatrics, made some remarks on the frequency of malignant forms of diphtheria during the last two years. The use of serum has, however, prevented the mortality being increased noticeably. The principal characteristics of these malignant forms are as follows: thick, extensive pseudomembranes, of a grayish or brownish hue, with swelling and redness of the parts situated beneath; considerable adenopathy, with periglandular œdema; temperature almost, if not quite, normal, weak pulse, deep nervous depression, the refusal to eat or drink, livid pallor, almost constant albuminuria. In these cases the serum does not produce an immediate effect, and death sometimes supervenes. This slow progress of the disease is what is most striking. Toward the fourth 'or fifth day the pseudomembranes have about disappeared, and the swelling of the glands is noticeably less pronounced. There are left, however, symptoms which indicate a cachectic period, and which are the following: (1) livid pallor, weak pulse, often paralysis of the palate, the child remaining motionless and dull; (2) increase of hepatic dulness as well as that of the heart in its transverse dimensions, the pulse becoming so rapid that it can no longer be counted; (3) vomiting preceding death, which comes on from syncope or asphyxia. Death does not come on in all cases, as a cure may take place when the heart is not too much dilated and the hepatic dulness not too considerable.

Death generally supervenes on the tenth day, but in one case it came as late as the thirtieth. The lesions found at the autopsy are always the same, such as myocarditis, apexian endocarditis and cardiac thrombosis in the right and left heart, situated near the apex and causing emboli in the brain, spleen, and lungs The liver is large, and covered with white spots. There is also hyperæmic or degenerative nephritis, congestion of the lungs and brain. In all these cases there is found in the blood a special diplococcus, which has been studied by Degny and Legros, and which seems to be quite distinct from ordinary streptococci. It resembles, to a certain extent, the diplostreptococcus found in scarlet fever, but can be distinguished from the latter by its mobility, lack of reaction on milk, and affinity for red corpuscles. This may be the cause of the symptoms seen lately in certain forms of diphtheria. Dr. Marfan insists once more on the necessity of making an injection as soon as possible.

In a recent article published in the *Presse Medicale*, Dr. Sayle, the assistant editor of this paper, recommended dental surgery as a specialty to young physicians. He remarked that nowadays it was necessary to show one's proficiency more by acting than by talking, and dental surgery was a field of work where this condition was requisite.

Before the laws of 1893 on the practice of dentistry had been passed any one could be a dentist. It is now necessary to obtain in France either a diploma of surgeon dentist or that of doctor of medicine. There are at present two dental schools in Paris, one in the rue de la Tour d'Auvergne and another in the rue de l'Abbaye. A certificate showing that one has had a common-school education is sufficient to enter either of these, and the course is of three years' duration. At the end of each year, and at the end of the course, examinations are passed to obtain the title, but to practise in France it is necessary to pass a State examination at the Faculty of Medicine before a jury composed of professors and dentists of the hospitals.

Doctors of medicine are supposed to know all that is requisite, and can practise dentistry without going through any examinations. The best dental surgeons in Paris are now those who take out the diploma of doctor of medicine and study at the same time dental surgery. They thus receive a degree of instruction, which makes of them thoroughly well-grounded specialists.

A recent case of death from perforation and consequent peritonitis in typhoid fever shows how sometimes hospital regulations are inimical to the best interests of the patient. A child had been admitted into the service of Dr. Graucher at the Enfants Malades Hospital, and his case was diagnosed as one of simple typhoid fever. Toward the end of the illness a perforation took place on the 17th of April, and next day it was decided to operate. It was, however, necessary to have the permission of the parents, and so the operation was deferred twenty-one hours. After having shown some signs of amelioration, the patient died on the 29th, and the autopsy, which was performed next day, showed the peritonitis had continued in the middle part of the abdomen. The physician in charge of the case did not doubt that if an operation had been carried out sooner the result might have been quite different.

Dr. Leopold Leir, who has been publishing several articles in the *Presse Medicale* on the treatment of different forms of arthritis by injections of the serum of Trunecek, has been using it in the form of enemata, and also as a powder to be taken by the mouth.

His formula is as follows:

Chloride of sodium	10
Sulphate of sodium	1
Sulphate of calcium	āā 0.75
Phosphate of magnesium	
Carbonate of sodium	0.40
Phosphate of sodium	0.30

To be divided into 13 capsules and one taken an hour before the first breakfast.

Dr. Lévy gives one or two and then again only half a capsule. Sometimes a slight degree of diarrhœa was caused, which was easily stopped by the use of a few drops of laudanum. The drug was also used in cases of paraplegia and of nervous symptoms simulating progressive general paralysis. In two cases of buzzing of the ears there was considerable improvement under this treatment.

At a meeting held by the French Society of Pediatrics on the 17th of June, Dr. Barbier and Alquier described the causes of death found in forty-five autopsies of children suffering from diphtheria. The most frequent is cardiac thrombosis, which existed in 50 per cent of the cases, the thrombosis almost always occupies the right heart In four cases the examination of the clot gave no result, in four cases the diphtheria microbe was found, the streptococcus alone in two, the staphylococcus alone in one, and the streptococcus and the bacillus of diphtheria once. Cardiac thrombosis seems to be frequent in severe forms of diphtheria, and occurs during convalescence, nine to fifteen days after the disappearance of the false membranes. Death is quite sudden, sometimes preceded by paleness of the face, by cyanosis, agitation, and anguish. Latent tuberculosis is often found, in eighteen cases out of 45, which makes a proportion of 40 per cent. In 25 per cent of the cases there were recent tuberculous signs, which had been brought on by diphtheria. Cardiac thrombosis does not, however, seem to be favored by tuberculosis, as the two were found together in only four cases.

The Maternity Hospital of Paris is being reconstructed on a relatively fine scale, and it can surely be said that Paris is, perhaps, the city that is most liberally supplied with these institutions. The new wards that have just been finished contain 114 beds and cost about $220,000.

Dr. Broca considers that immobilization of the knee and massage are sufficient treatment in simple hæmarthrosis. He describes, with a great deal of care, the fractures of the elbow-joint, speaks of some interesting cases of exostosis during growth, and devotes several lessons to osteomyelitis, and neurosis of the lower maxillary. Dr. Broca always considers it well to remove sequestra through the mouth. Three lessons are given over to the discussion of the treatment of appendicitis and its complications. Dr. Broca was quite radical in his mode of intervention from 1892 in 1895. He used to operate the children a few hours after they had been brought to the hospital. Since 1896 he has, like Dr. Jalagnier, become more reserved, and his results are, it seems, much better.

Progress of Medical Science.

The Boston Medical and Surgical Journal, September 4, 1902

The Changes in the Spinal Cord and Medulla in Pernicious Anæmia.—The conclusions drawn by Frank Billings from a study of this subject are as follows: (1) There is a well established relation of diffuse cord degeneration with pernicious anæmia; (2) It seems highly probable that the hæmolysis and the cord changes are due to the same toxin; (3) While the source of the toxin is unknown the fact that gastro-intestinal disturbance is so common in the disease would lead one to suppose that it is of intestinal origin; (4) The diffuse degenerations of the spinal cord which occur in conditions without pernicious anæmia do not appear to differ essentially from those of pernicious anæmia; (5) It is possible that a common blood-circulating poison exists which may expend its force upon the blood in one individual, upon the nervous apparatus in another, and coincidently upon the blood and spinal cord in others.

Appendicitis Complicating Pregnancy.—Francis D. Donoghue reports a case of removal of gangrenous appendix at three and one-half months, followed by successful delivery at term of an eight pound child. He attributes the happy result in this case directly to the early recognition of danger signals, followed by prompt action, and says that in view of the serious nature of this complication we are justified in insisting upon immediate operation if the attack occurs during pregnancy, and also upon operation in all cases where appendicitis has occurred in women who are susceptible of becoming pregnant. The diagnosis of appendicitis complicating pregnancy should ordinarily be easy, not differing materially from an uncomplicated case. The most important diagnostic signs are localizing pain, muscular rigidity, and the elevation of pulse or temperature. The diagnosis should be followed by immediate operation, as the danger not only to mother but to fœtus increases rapidly with the increase in sepsis. In operating the writer thoroughly believes in the rectus incision for the following reasons: It is fully as easy to reach the appendix in this way; the incision is easy to enlarge without cutting muscle fiber, and in healing there is a constant tendency of the rectus fibers to close the opening. If this incision is used and properly closed, there will be little danger of rupture before, during or after delivery.

Vaccination Eruptions.—Harvey P. Towle says that the literature of this subject contains surprisingly few references, and much difference of opinion as to what should be called a vaccination eruption, as some authors include under this head any eruption which occurs during or even after the course of the vaccinal lesion. Others use the term for those eruptions only which occur during the course of the vaccinal lesion and which have no other obvious cause than the vaccination. The author quotes Sobel as defining properly what he means by a vaccination eruption: "We must not confound eruptions pure and simple (in which it may be reasonably assumed that the course of the vaccination has been instrumental in the production and development) with those produced by extraneous infection (which would in all likelihood have occurred without the inoculation of the virus), impetigo contagiosa, erysipelas, abscess, furunculosis, etc. I should reluctantly attribute any generalized eruption to vaccination once the seat of inoculation has become thoroughly healed. So long as the sore remains open, so long as there is a chance for absorption, generalized vaccination rashes may occur." It is in accordance with this definition that the author considers the subject. He gives a review of five cases seen by himself in the last six months. The first case was one of secondary local inoculation which followed the scratching of the lesion by the patient. Three of the cases presented an eruption which appeared from the sixth to the thirteenth day, in patients whose vaccination lesions were still secreting—these cases all had in common redness, slight induration, lesions of a rounded character, a short duration and no marked constitutional disturbance. In the fifth case a recently healed psoriasis reappeared two weeks after vaccination, and the author says that while it is clear that the vaccination was not the cause of the eruption itself, it is a question if the vaccination did not so upset the equilibrium of the skin as to cause a rapid and widespread recurrence.

Journal of the American Medical Association, Sept. 6, 1902.

Psychology of Habit in Surgical Technique.—R. C. Coffee discusses the various phases of this question, and lays down the following rules: (1) Avoid contact with septic material the same as if you had no water, no chemical antiseptics, and no artificial protection for the hands. (2) In preparing the hands or a field for operation, do your work as thoroughly as if you had handled the most virulent septic material and had no antiseptic solution or artificial protection for the hands. (3) Use chemical germicides as faithfully as if you had handled septic matter, had not had the opportunity of using soap or water, and had no rubber gloves. (4) When rubber gloves are used, no less precaution should be exercised than if they were not to be used. (5) After these steps have been followed out, avoid contact of the supposedly sterilized articles the same as if no cleansing had been done by either of the preceding methods.

Medical News, September 6, 1902.

Some Notes on Tricuspid Diseases.—Thomas E. Satterthwaite states that next to pulmonary valve diseases serious affections are the most uncommon. They are very rarely single. Organic lesions of the tricuspid valve due to endocarditis or atheroma are usually preceded by mitral or aortic diseases or general arterio-sclerosis. Insufficiency and stenosis are the two recognized lesions, the former being the most common. It may be congenital or acquired, organic or relative. The latter preponderates. The most characteristic sign of tricuspid insufficiency is the systolic murmur over the tricuspid area. It is usually soft and faint. Tricuspid insufficiency produces at first dilatation and then hypertrophy of the right auricle. But it is seldom recognized in life even under favorable circumstances. Epigastric pulsation is an important sign, as is also faintness of the second pulmonary sound. In general the prognosis is bad. In tricuspid stenosis, an important feature is that the great majority of patients are women. The average age at death is between thirty-one and thirty-six. Rheumatism is the most frequent factor in the etiology. The disease has an insidious advancement. The patient will complain of palpitation. In one-half of the cases there is cyanosis, which is apt to be extreme. Mental confusion has been noticed. Diagnosis is most difficult. The general prognosis is worse than in any other form of valvular disease. In general, the louder the murmur, the less the danger.

Embolism of the Mesenteric Artery.—Alexander Lambert and W. B. Coley present this paper. Embolism of the mesenteric arteries is extremely rare. The writers report the following: The patient was a young man, thirty-four years old, with a decided alcoholic habit. During an alcoholic spree which had lasted for four days, he was awakened at night by severe general pain in the abdomen, not localized. At this time there was no nausea or vomiting. Three hours later he took one-quarter grain of morphine and went about his work. The pain increased and he took a large saline cathartic. The pain continued with exacerbations through the day. Cathartics and enemeta were productive of no result. There was marked abdominal distention. The diagnosis of acute intestinal obstruction was made. The cause was impossible to determine. Operation was advised. Towards evening the abdominal distention was increased; pulse was 106; temperature was 99°F. At eight o'clock A.M., the vomiting had become slightly fæcal and the symptoms just enumerated were more grave. Prostration was extreme, though the patient was conscious. The diagnosis was still doubtful. Operation was performed at half-past eight in the morning by Drs. William T. Bull, and John B. Walker. A large fold of mesentery of the small intestine was found to be greatly thickened. The diagnosis of thrombosis of the mesenteric vessels was made. Peritonitis had begun to develop, and no further surgical interference was attempted. The thickened mesentery was as large as two hands, and supplied several feet of intestine. The wound was closed and the patient returned to his bed in fair condition. He died at 4 P.M. about seven hours after operation. Autopsy was performed and the causes of death were stated to be: Multiple infarctions of mesenteric and pulmonary arteries, following thrombosis of the right auricle. Complicated by marked general atheroma and by extreme fatty degeneration of all visceral parenchyma, notably of the heart muscle, all probably resulting from alcoholic toxæmia. Chronic appendicitis.

A Brief Consideration of the Scientific Treatment of a Few of the Diseases of the Heart.—I. Newton Snively believes that it is often better to give no medicine for heart lesions. In considering the enlarged heart in which no valvular or orificial lesion exists, the differential diagnosis may be very obscure, but the treatment is indicated as much by the general state of health of the patient as by the heart conditions. Such treatment should be, in general, as follows: The cause of the degeneration should be removed, if possible. The patient's hygienic and dietetic treatment should receive due consideration, so as to improve his nutrition. In some cases digitalis should be employed, especially if the patient shows signs of commencing dilatation. In other cases (if anæmic) hæmatinics with arsenic and strychnine are the best remedies. Some of these cases do well under skilfully-directed physical exercise and light gymnastics, increased or decreased according to the peculiar effect upon the patient. If the patient is suffering from obesity, then Oertel's treatment may be followed: Reduction of the amount of liquid taken with the meals and during the intervals; frequent bathing (Turkish baths, if practicable); the diet is made up largely of proteids, and exercise should be gradually increased from day to day. The writer sums up his paper as follows: Each patient showing a heart lesion must be a study unto himself. No heart medicine is needed unless the myocardium is unable to do its work in a physiological way. The heart muscle should demand more consideration than the heart murmur. Rest is one of our best therapeutic agents. We should try by every possible means to prevent myocarditis in all diseases where this condition is apt to arise. After any severe diseased process we should insist upon the patient resting in bed long enough to allow the myocardium to be restored. We should improve the general nutrition of our patients and restore the blood to a normal standard by the use of blood tonics. We should investigate the kidneys in all cases showing signs of cardiac incompetency. Physical exercise, light gymnastics, and properly-selected diet are valuable aids in the treatment of cardiac disease.

Characteristics of Pulmonary Valve Affections, with Cases.—Thomas E. Satterthwaite states that of all cardiac valves, the pulmonary is least often affected. Very rarely it is a single lesion. The form most commonly seen in adult life, is insufficiency; in fetal life or infancy, stenosis. In adults, diseases of the pulmonary valve generally follow endocarditis of other valves, or arterio-sclerosis. While temporary insufficiency is common, the chronic form is not common. It frequently happens that the lesions of the right heart escape the notice of the physician. In some cases pin-hole openings in the valves are found at autopsy as the result of congenital malformation. Although these minute holes do not give rise to murmurs, large openings may do so. From the fact of its proximity to the aortic, the pulmonary area, more than all other valvular areas, is more likely to lead to error. In certain cases aortic murmurs may be heard best over the pulmonary area and *vice versa*. Or they may be clearest above the second cartilage or over the sternum opposite to it. Other murmurs in the pulmonary area are due to anæmia, change of position, and other causes, which are in no way, as far as known, connected with the valves. Auscultatory signs in this area should therefore be carefully weighed. In the case of congenital insufficiency of the tricuspid there is apt to be found also pulmonary stenosis and insufficiency. Insufficiency may occur at any age. Sex seems to have no influence. Ulcerative endocarditis has been given the chief place in the etiology. This may result from gonorrhœa, pyæmia, puerperal fever, and pneumonia. Other causes of the lesion are pulmonary stenosis, aortic aneurysm, pulmonary dilatation, or some abnormal condition of the valves. Insufficiency from stenosis may be due to adhesion of leaflets. Abnormalities, such as clubbed fingers and toes, and an abnormal development of the chest, together with a condition of general cyanosis, will call attention to the congenital form which is most apt to be associated with stenosis and cardiac anomalies. In such cases the murmur is soft because the blood current is not vigorous and there are no ulcerations. Signs of defective nutrition are very apt to be noted in the acquired form. In congenital disease the prognosis is unfavorable. In acquired cases the patient sometimes reaches old age. Pulmonary stenosis is very rare as a single congenital lesion. Diagnosis of pulmonary stenosis is never easy. Prognosis is never good in the congenital forms, although it is more favorable in the acquired form. At the birth of these infants, after the mucus has been cleared from the mouth and nostrils, circulation should be stimulated and artificial respiration instituted. In the acquired form, rheumatic tendencies and infections should be combated, and the cardiac symptoms should be treated as they arise.

New York Medical Journal, September 6, 1902.

The Use of Electricity in the Treatment of Habitual Constipation.—Taking into consideration the fact that of twelve cases reported, 75 per cent. were completely cured, S. Cohn offers the following conclusions: (1) Electricity should not be employed as a last desperate chance after all other means have failed, but should be given a front rank in the treatment of this disease; (2) Especially the static currents, with their powerful vibratory effects, should be employed more frequently than has been done heretofore; (3) The reduction of abdominal circumference by the use of these currents is a proof of their tonic influence upon the abdominal muscles; (4) The most powerful means of obtaining this tonic condition is the administration of the swelling or undulating current.

A Résumé of Forty-eight Cases of Post-operative Crural Thrombosis.—B. B. Schenck enumerates the cases which are taken from the records of the Johns Hopkins Gynecological Service. From a study of these cases he comes to the following conclusions: Thrombosis of the crural veins is more common after pelvic operations than is generally recognized. It occurs more frequently in those cases in which large tumors, springing from the pelvic organs, have been removed. It rarely follows extrapelvic operations. In this series it has been infrequent after infected cases. The anæmia and cachexia in consequence of new growths seem to be factors in its causation. Constipation and the use of enemata play a doubtful part in the ætiology. Traumatism at the time of the operation should be borne in mind and deep retractors used with extreme care. Infection is undoubtedly of great importance, but its frequency is difficult to decide. This complication often occurs when least expected and usually late in convalescence. Albumin in the urine is more frequent in these cases than in those running an uninterrupted course. The pulse curve of Singer does not always occur. The results of rest and elevation for the full length of time are excellent. When the time is lessened, swelling and pain persist, and the danger of pulmonary embolus is increased.

Clinical Notes on Cardiac Diseases.—R. R. Cornell reports a series of cases showing, among other things, that the physical signs pertaining to the condition of the heart may not become evident till an acute affection of the pericardium has developed. Thus in one case an attack designated pericarditis was really a pleuropericarditis. This lesion resulted in such an adherence of the pleura as caused retraction of lung tissue, and affected an exposure of the heart to the extent that its physical signs became apparent. Four cases of angina pectoris are reported, but none of them presented any unusual features. The last case was one of pericarditis following rheumatism giving a function murmur, extending from the third left rib, close to the sternum, downward and outward to a point somewhat to the left of the cartilage of the fourth left rib, and by the obscuring of the sounds of the heart at the apex. The murmur was audible for five days, and then disappeared. All sounds of the heart at that time were so hidden as to be scarcely heard. Yet percussion of the superficial and deep cardiac areas demonstrated no enlargement of the heart in any direction. But suddenly, upon the night of the tenth day of the pericarditis, a sound completely resembling that produced by the churning of milk emanated from the patient's chest. It could be heard at a distance of five feet from his body, and suggested the presence of a pericardial effusion that was being churned by the heart. Examination with the stethoscope revealed these signs as existing in an intense degree over the entire region of the heart. Percussion, however, indicated no enlargement of the heart. An exploring needle was introduced into the pericardial sac beneath the fourth rib, at the left border of the sternum, and brought away nothing. According to the author, the churning sound was not due to pericardial effusion, but was caused by the cardiac impact against a stomach over-distended with gas. This he considers proven by two facts: First, the sound stopped when the stomach was freed from the gas and second, because after death, the next day, the pericardial sac contained only two drams of serum. The problem in this case he considers to be the subsidence of the pericardial friction murmur without the formation, in considerable quantity, of serum, or the absorption of the whole or the greater part of the fibrinous exudate.

American Medicine, September 6, 1902.

Rupture of the Heart.—R. L. Leak gives a report on this subject, grounded on his experience, since 1891, in the St. Lawrence State Hospital at Ogdensburg, N. Y. In 560 autopsies there were found to be five cases in which death was due to rupture of the heart. The ratio, therefore, was 1 to every 112 deaths. The writer gives a table of these cases which he reports, which sums up various interesting points in regard to them. Three of the cases were women; two were men. In two cases the arteries are described as fibrous; in three, very fibrous, almost calcareous. In two cases the pulse was 88; in two, 72; and in the fifth, 120, but strong. In two cases the heart was hypertrophied; in two, normal; and in one there was a systolic murmur. The physical condition was poor in two cases; emaciated, good, and fair in the others. The weight was 118, 79, 101, and 119 pounds in four cases, respectively. Necropsy showed the weight of the heart in the five cases, respectively: 9½, 9, 10½, 13, and 17 ounces. The place of rupture was in the left ventricle in four cases, and in the right auricle in one case. Microscopic examination gave the following results in three cases: Fatty and granular degeneration; marked brown atrophy transverse striations, lost granular degeneration, cells fragmented, capillaries sclerosed, cellular infiltration; slight granular degeneration, marked increased connective tissue, and capillaries sclerosed.

Atresia of the Vagina (Colpatresia), Unilateral Ovary and Tube, with No Uterus.—Charles E. Barnett describes a case of this kind. This abnormality is due in some way to a lack of development embryologically of the lower third of the Müllerian duct on one side, and the upper part of the Wolffian duct and body on the other. The patient was a woman aged thirty-three years. Her hips were somewhat small, and her face was effeminate. At thirteen years of age she had cramp in the uterine region, from which it took six months to recover. She gave a history of monthly recurrence of pelvic cramps till one day, during a paroxysm, her nose began bleeding violently. After losing much blood the pelvic pain subsided. This vicarious menstruation continued up to the time of operation. An aunt had vaginal atresia. On examination the vulva was found normal, except a slight enlargement of the clitoris. There was no hymen. The vagina was one and one-half inches long, and small in caliber. There was a firm membranous body in the uterine region, which seemed to be the uterus. The right Fallopian tube was enlarged to probably three times its normal size, and led to the right ovary, which was distinctly felt. No left ovary or tube was discovered. Operation was performed. An opening was made through the vaginal septum into a musculo-membrano-cartilaginous pouch, out of which a dark menstrual fluid came. The Fallopian tube could be sounded through this passage. The pouch in the lower part of the tube was washed out and packed with gauze. The results of the operation were excellent. The vagina was enlarged, and menstruation was established by the normal route on the fifteenth day after operation. Flow has occurred in the same manner for eleven months, with no unpleasant symptoms. The patient has gained both flesh and strength. The writer concludes that the retained fluid from the first menstruation produced a parasalpingitis and endosalpingitis, with pelvic peritonitis. Nature, in six month's time, formed a pouch that was sufficiently impermeable to require a longer time for absorption of the fluid, and consequently less toxicity occurred therefrom. Epistaxis depleted the body and relieved the congestion, the Fallopian tube supplied the uterine dificiency and did the menstruating. It is easy to conclude that coitus is contraindicated.

Philadelphia Medical Journal, September 6, 1902.

The Climate of Porto Rico.—T. L. Coley presents a valuable resumé of the climatic conditions of Porto Rico. This island is situated entirely within the torrid zone, between the latitudes of 17° 54″ and 18° 30″ north. Its longitude west of Greenwich is between 65° and 67°. It is a comparatively small island, and is swept by the trade winds; it is also far from the warm waters of the Gulf Stream; and so natives of the temperate zone may live there in comfort after they have become acclimated. The island is ninety-five miles long, by thirty-five miles wide. The mountain ranges reach a height of 2,000 feet above the sea level. The climate, while tropical, is not torrid. The heat is continuous, though not extreme. and the climate is somewhat enervating. The winter season extends from October to March, inclusive. The air is delightfully fresh during the winter season. The difference between the temperature in open sunlight and dense shade is extremely marked. As a residence for natives of temperate climates, Porto Rico is far preferable to any other island of the West-Indian group. Yellow fever has never been present in an epidemic form. Typhoid fever is common. The secondary anæmias are prevalent. The death rate is high, due rather to the character of the population than to the climate. Sanitation was practically unknown prior to the American occupation, but conditions are now much better. The potential possibilities are promising.

The Treatment of Uræmia (Mixed Toxæmia).—Egbert H. Grandin believes that rational therapeusis has been much retarded by the idea that it is in the kidneys that the poisonous element is manufactured, which is at the basis of the symptomatology to which the term uræmia has been mistakenly applied. He believes that this symptomatology is dependent upon a toxin emanating in part from the kidneys, in part from the liver, in part from the intestines, and, in pregnancy, in part, possibly, from the body of the fœtus. The writer sums up the therapeusis in two words—elimination and derivation. The treatment of this mixed toxæmia may be ranged under three headings: The prophylactic—the treatment which aims at warding off toxæmia; the emergency treatment—that which is applicable in the presence of toxæmia; and, lastly, when pregnancy exists, the surgical treatment. The chief point in prophylaxis is to spare the kidneys and intestinal canal as much strain as possible. The sweat glands should be made to work well, and free action of the liver should be secured. When toxæmia is active, chloroform is valuable. The one occasion in which surgery enters as an adjunct in the treatment of toxæmia, is when the phenomena are a complication of pregnancy. The uterus should be evacuated, and then be allowed to relax, so that blood is lost—a form of venesection which is most useful. The writer concludes his paper by summing up the therapeusis in the words: Dietetic, hygienic, eliminative, and derivative.

A Note on Some Psychoses of Early Puberty, with Report of a Case in a Boy, Twelve Years Old.—Alfred Gordon declares that when puberty approaches, a physiological crisis takes place in the life of the child. The intellect begins to predominate over the instinct or sentiment. The transition from childhood to puberty is very favorable for development of hereditary affections. The changes at this time in the intellectual and physical spheres are often the source of various psychic disturbances. Mental disorders may be various. They may be in the form of a pure psychosis, mental degeneracy, dementia præcox, etc., There is a form of psychosis, rare in late childhood or early puberty, in which the disturbances occupy an intermediate state between the neuroses or psychoses and true insanities. If these patients do become insane, they may remain so permanently or recover only temporarily. Their mental or nervous equilibrium has not a solid basis, and is constantly threatened with a break. They are Morel's degenerates. The writer refers to those degenerates whose mental symptoms are only episodic in character, symptoms which prevent psychopathic disturbances, but with total lucidity of mind. He then describes a case of this kind. The ensemble of the psychoses which this patient, a boy of twelve years, presented, developed on a hereditary and neuropathic basis and coincided with the transition of childhood to puberty. Through all his experience of doubts and obsessions his intelligence was unaltered. He was perfectly conscious of his sufferings. It was a sort of psychological paradox. The patient was really a superior degenerate, and was probably threatened with dementia præcox.

British Medical Journal, August 30, 1902.

The Subcutaneous Administration of Carbohydrates.—C. Nepean Longridge declares that to be suitable for subcutaneous injection a food must be: (1) Capable of sterilization and assimilation, and (2) non-irritating, fluid, and of moderate bulk. According to Barker, solutions of carbohydrate to be non-irritating, must be adapted to the osmotic conditions of the part selected for injection. The liver possesses the power of eliminating or changing into comparatively innocuous forms poisons which are conveyed to it by the blood stream. The evidence is partly experimental and partly pathological. It is supposed that the liver is injured in its efforts to cope with the poison. The antitoxic function of the liver ceased to be exercised in the absence of glycogen. The power of the liver to decrease the toxicity of poisons depends directly upon the amount of glycogen which is contained in its cells. Glucose is well borne when given with albumen water and a little lemon juice. Even if it does not increase the antitoxic function of the liver it can always act as a saver of proteid.

Subcutaneous Injection of Quinine in Malarial Fevers.—Arthur D. Humphry describes his method: The injection is given before 8 A.M.; in a teaspoon, about twenty drops of water are well boiled over a spirit lamp. In this is dissolved a three-grain tablet of bihydrochlorate of quinine, the solution again boiled, and then allowed to cool. The skin is well cleansed, and the syringe is sterilized. The needle is then plunged deeply into the muscle; the deltoid in adults, the gluteus in children, being chosen. The writer never hesitates to use this method in acute cases, accompanied by constant vomiting, or in cases of some standing which do not respond to quinine in large or small and frequently repeated doses given by the mouth. The writer then reports several cases. He has always met with success in the use of this method. The site of the injection has been followed by some deep-seated induration, which has generally disappeared in the course of a few days.

A Case of Second Eruption in Vaccina.—W. H. B. Stoddart reports the following case: The patient was a man aged twenty-nine years. He had been vaccinated in infancy, and this had been followed by a rash, which seemed to be eczematous in nature. He was next vaccinated at the age of thirteen. This was uneventful. The next vaccination was performed last winter. Calf lymph was used in two places on the arm. Both places took well and the scabs fell off at about the end of the seventh week. About ten days after this, one of the places became irritable, and in the course of forty-eight hours a clear vesicle had formed. This was about half an inch in diameter. To determine, if possible, whether the recrudescence was of the nature of true vaccina or not, a second individual was vaccinated from the first patient's vesicle. The second patient had been vaccinated in infancy, and in 1891 successfully. In 1894 he was vaccinated without success. Nothing happened for eleven days. Then B's arm became irritable, and a large bleb formed similar to the one on A's arm. When the scab had disappeared from B's arm, he and another man, who had not been vaccinated since 1891, were vaccinated from the same tube of calf lymph. The vaccination of C's arm was successful, but that of B's was unsuccessful. He had evidently been rendered immune. This would appear to show that the second eruption in the case of A was a true vaccina, and might have been a relapse. One argument contrary to this view is that neither the second eruption on A's arm nor the first eruption on B's arm bore the slightest resemblance to an ordinary vaccinal eruption.

Deutsche medicinische Wochenschrift, August 14, 1902.

Erythema Simplex Marginatum.—Leopold Feilchenfeld reports six instances in which he observed a form of erythema, to which he has given the above name. All of the patients were children, and were apparently in the best of health. The disease is apparently infectious in nature, since five of the patients lived in close proximity to one another. The cutaneous lesion consists of a diffused redness and swelling of the skin in the involved region. The boundaries of the eruption show a sharp line of demarcation. Usually the patients complain of more or less burning or itching. The redness can be made nearly to disappear upon pressure, but quickly returns after this is removed. As a rule, the eruption only appears upon the face and extensor surfaces of the upper extremities, but it is occasionally seen upon the back. Constitutional symptoms may be entirely absent, or there may be slight fever with its attending concomitants. In one of the cases an angina of moderate severity accompanied the attack. The average duration was eight days, at the end of which time recovery took place spontaneously. The author believes that this variety of erythema is to be regarded as a form of this affection which has not as yet been described; especially is it to be differentiated from erythema medicamentosum and erythema exsudativum marginatum.

Tumor of the Cauda Equina.—Franz Volhard reports a rare case. The patient had been sick for some years, the first signs of illness being disturbances of the bladder functions. Gradually incontinence of urine supervened, and finally dilatation of the bladder and a secondary pyelitis. The patient first applied for treatment because of dyspeptic symptoms. At that time there were present marked motor disturbances in the left ischiadic territory. Disturbances of sensation were to all practical purposes absent. The reflexes on the affected side were absent, with the exception of those of the patella and pupil. Much difficulty was experienced in arriving at a diagnosis, but by the means of a careful study of the motor disturbances, the location of the lesion was finally assigned to the cauda equina. The nature of the lesion was still somewhat a matter of speculation, but it was regarded, principally on account of the clinical history, as most probable that it was a non-malignant tumor. An operation was decided upon, but before this could be undertaken, the general condition of the patient suddenly became worse, and in a few days death supervened. Upon autopsy the diagnosis was verified. Microscopical examination showed that the tumor was a lymphangioma cavernosum. So far as the author knows, this is the first instance in which a tumor of the cauda equina has been diagnosed ante-mortem and the diagnosis proved post-mortem.

Repair of Bony Defects of the Skull by the Transplantation of Bony Plates Taken from the Neighborhood of the Lesion.—E. Hoffmann says that in repairing bony defects of the skull the best results are to be obtained by taking the bony transplants from the neighborhood of the defect rather than by utilizing foreign substances (prepared bone, metals, etc.), or bony transplants from other regions of the body. All foreign substances have the disadvantage that at any time subsequent to their implantation suppuration is liable to occur, and the results of the operation thereby nullified. When bony plates are transplanted from regions of the body which are removed from the defect, as has been recommended by Müller-Koenig and Seydel, we are compelled to make a new lesion, the effects of which must be recovered from by the patient. The method here advised by Hoffmann possesses neither of these disadvantages. The technique of the operation freshening the margins of the defect when such is of long standing, removing the soft parts from the immediate neighborhood, and transplanting a sufficient portion of the lamina externa thereunder to completely cover in the defect. The whole is then covered by the surrounding skin, which is accurately sutured. The success of the procedure depends principally upon two factors: (1) The observance of a rigid asepsis or antisepsis; (2) An intimate proximity of the transplanted bone to the margins of the defect. The indications for the operation are as follows: (1) In all trephinings of the intact skull, when Wagner's method is not available, or for any reason the resected bone cannot be reimplanted. (2) For the reparation of defects of the skull caused by traumatism or tumors. (3) In the primary treatment of complicated fractures of the skull when pieces of the bone are lost, or are not suitable for reimplantation from any cause. (4) For the reparation of defects of the skull which are the sequelæ of suppurating fractures of the same. Here the only condition necessary is the availability of a sufficient amount of skin with which the wound may be closed. (5) For the reparation of defects of the skull which arise as the result of tuberculous or syphilitic infection. Here the same condition is necessary as indicated under the previous indication. One case in which the defect was traumatic in origin is reported in detail.

Berliner klinische Wochenschrift, August 18, 1902.

Prognosis of Tuberculous Meningitis.—Alfred Gross says that the more extensive employment of lumbar puncture has shown that tuberculous meningitis is not nearly so fatal a condition as was formerly supposed. The author reports a case in which, by a strained preparation, he detected the presence of three tubercle bacilli in the fluid withdrawn by lumbar puncture on the third day of the disease. None of these organisms were found in similar fluid withdrawn on the eighth and tenth days. Cultivation of this fluid upon Agar and Loeffler's blood serum showed it to be sterile. No animal inoculations were tried. The patient recovered after sixteen days of sickness. Shortly thereafter a physical examination of the lungs showed consolidation at both apices. In the sputum no tubercle bacilli were found. The author regards the diagnosis of tuberculous meningitis as sound.

A Case of Osteomyelitis of the Occiput Which Closely Resembled a Meningocele.—W. Schrank reports the case of a four-and-a-half-year-old boy, who received a fall upon his head, but no appreciable local lesion was caused thereby. Shortly thereafter the hair began to fall out over the injured region, and soon a small tumor made its appearance in the same location. This tumor gradually increased in size, and the general condition of the patient began to suffer. Exploratory puncture showed that the tumor contained a thin, blood serous fluid, and the diagnosis of meningocele was made. Upon examination the tumor was found to be partially reducible, and treatment by a compression bandage was at first instituted. This, however, was without result, and the general condition of the child continued to decline, so that operative procedures were advised. The temperature and pulse had been normal throughout the entire course. Upon operation it was found that the lesion consisted of an osteomyelitis of a considerable portion of the cranial bones located at base of the tumor. All of the necrotic tissue was removed and complete recovery took place. It is interesting to note that following the operation the pulse rate was very high (120 per minute) for three weeks, although the temperature remained normal throughout.

Credé's Method of Treating Ophthalmia of the New-Born.—G. Leopold enters into a review of the literature, and gives his own experiences with this method of treatment. Cramer has been most pronounced in his condemnations, claiming that the nitrate of silver solution in a large number of instances produces in itself an inflammation of the conjuntivæ, which is frequently very serious, often giving rise to incurable sequelæ. A perusal of Cramer's article shows that the technique employed by him is not the same as that recommended by Credé. Cramer, after dropping the silver solution into the internal canthus, opens and closes the eyelids with the fingers a number of times, so as to secure an equal distribution of the fluid. It is certain that in this way much irritation is produced, and if inflammatory lesions arise they are certainly due to the traumatism, rather than to the silver solution. Credé advised that the fluid be dropped directly upon the cornea, and that all manipulation of the eyelids be withheld. If these instructions are carefully followed, abundant experience has shown that subsequent inflammation is of the rarest occurrence. Manifold statistics prove the efficiency of the method as advised by Credé. In all institutions where it is used blenorrhœal ophthalmia is to-day a rare disease. Out of 2,146 births which occurred in the author's clinic in 1898, in but three did ophthalmia develop. In all of these a 2 per cent. solution was used. Since the beginning of 1902 a 1 per cent. solution has been exclusively used by the author. Six hundred and ninety-eight births have taken place, and only one case of blenorrhœal ophthalmia has occurred. In none of the cases was any inflammation due to the silver noticeable. In a few there was a slight irritation, which lasted twenty-four hours and disappeared without the necessity of treatment. It has recently been proposed to substitute the acetate for the nitrate of silver in the strength of a 1.24 per cent. solution. This has been tried by the author with satisfactory results, but it cannot be said that it possesses any advantages over the nitrate solution.

French and Italian Journals.

Paracentesis of the Pericardium.—Aldo Tozzi says that so far eighty cases of this operation have been reported, and he now reports the eighty-first. The patient, a man of sixty-six years, was suffering from gravel hydropericardium, with insufficiency and stenosis of the mitral valve. An incision was made in the fourth intercostal space of the left side, and about 600 c. c. of fluid removed. The author has found by experience that it is not necessary to remove all the fluid present, for the removal of a moderate amount will promote the absorption of the remainder. Six years after the operation the patient was in excellent condition, the heart lesion being perfectly compensated. Tozzi urges more courage among practitioners in regard to the performance of this operation.—*La Riforma Medica*, August 12, 1902.

Vaccination against the Plague by Way of the Stomach.—In view of the determined opposition of many people to cutaneous vaccination, Mercatelli Vincenzo experimented with guinea-pigs in order to ascertain whether it might be possible to obtain the desired results by the administration of a bolus of anti-plague vaccine by the mouth. Large doses determined a toxic gastroenteritis, which in some cases ended fatally. Absorption of the vaccine was accompanied by hypothermia reaching 2 degrees C. below normal, and lasting from ten to fifteen days in favorable cases. The animals which survived the treatment exhibited a slight degree of immunity toward inoculations of plague virus; this occurred after one dose only of the vaccine, and the author believes that by repeated progressive doses better results might be obtained. It is his purpose to carry on a series of experiments directed to this end.—*La Riforma Medica*, August 5, 1902.

Society Reports.

TWELFTH CONGRESS OF FRENCH-SPEAKING NEUROLOGISTS AND ALIENISTS.

Held at Grenoble, August 1 to 8, 1902.

THE twelfth congress of French-speaking neurologists and alienists was brilliantly opened on Friday morning, the first of August, at 9 o'clock, at the Hôtel de Ville. M. Régis presided. Near Dr. Régis of Bordeaux, the president of the Congress, were seated Dr. Gilbert Ballet, professor of the Faculté of Paris; M. Mottet, representing the prefect; M. Boirac, rector of the Academy; Dr. Bonnet, physician in chief of the asylum of St. Robert, and general secretary of the Congress; Dr. Bordier, director of the School of Medicine. There were besides, numerous other professors and foreign physicians, among whom were Messrs. Joffroy, Brissaud, Bourneville, Deny, Séglas, Legrain, A. Marie, and Chervin of Paris; Pierret and Carrier of Lyons; Ladame of Geneva; Fontanille, attorney-general of Grenoble; Sixto-Arman of Oviedo, Spain; Obrégia of Bucharest; Mendessholn, professor of physiology, at Saint Petersburg; and Crocq of Brussels.

In the absence of the mayor, M. Gontard gave the address of welcome. He was followed by Dr. Régis, who delivered a most interesting address. After visiting the Hôtel de Ville, and the Musée-bibliothèque, the members of the Congress assembled at the School of Medicine of Grenoble, where they were received by Dr. Bordier, director of the school, who delivered a very entertaining address. He pointed out the advance that has been made in the branch of medicine in which the members of the congress were specially interested, even the term neurologist indicating progress. Psychiatry was formerly regarded as a sort of sorcery. But to-day the affections of the brain and spinal cord are considered from the same point of view as the heart, the kidney, or the liver. Whereas only a few years back such terms as spirit, demon, and perturbation of nervous force were made use of, the present neurologists and alienists used sclerosis, thrombosis, and often also autointoxication. Mental troubles, such as those of sensibility and motility, were referred back to the nutritive processes or to chemical intoxications as a cause. However, even yet in spite of all the progress which had been made in this branch of medicine in the last few years, it was not always possible to distinguish with certainty between the malingerer and the real patient. But psychology, had become a chapter of physiology in which the habitual method of induction was used. Facts and observations were brought together, forming at last a vast synthesis. By making a biological science of psychology, order was beginning to shape itself out of the chaos of ancient metaphysics. The relation between the motor troubles of Addison's disease and the disturbed function of the suprarenal capsules had been traced; it was myxœdema and the cretinism of goiter which had suggested the idea of the functions of the thyroid body; it was the knowledge of the lesions of the third frontal convolution of the brain that made Broca the discoverer of the key to cerebral localizations. From the day when psychology became biological, it also became experimental. Thought was weighed and measured and analyzed in its genesis and in its structure. The physician was accustomed to consider the genesis and the evolution of form and of phenomena, to recognize especially the action of natural forces, it might be at the time when they give birth to organisms, or it might be at a later time. He was accustomed to weigh the laws of heredity in the consideration of individual variations. He contemplated men and things with an equitable and tolerant eye. He was convinced by experience that everything in nature was relative and contingent. He knew that every phenomena had its effect and its cause. It was due to the neurologist and the alienist that what was formerly considered the occult domain of medicine was now being cleared and enlightened by the rays of scientific research.

The Anxious States in Mental Maladies.—M. G. Lalanne of Bordeaux presented this paper, and in it he reviewed the states of anxiety observed in the course of the various psychical troubles. In his introduction he stated that the condition of anxiety was a malady in which the suffering was due primarily to circulatory and respiratory troubles. This painful condition presented degrees of intensity from a condition of simple apprehension with restlessness in the limbs, to actual pain located in the præcordial region, or even a feeling of suffocation, with pallor of the face, cold sweats, and fear of immediate death. This suffering might be observed even in healthy persons who were subjected to sudden misfortune or to the expectation of some great trouble. The term anxiety ought to be defined, but the literature would be searched in vain to find a clear and precise definition of the term and what it comprised. The best definition was found in clinical study. There were few conditions so difficult to conceal as anxiety. As well in its slightest degree—uneasiness or restlessness, as in its greatest intensity—anguish, anxiety was an emotion which was expressed by the entire being. There was no necessity of describing the anxious facies. The principal troubles which were associated with anxiety were physical, emotional, and mental. In the last few years there had been a decided tendency to unite the psychological with the clinical. These conditions of anxiety in mental troubles, whether of the slightest or of the most extreme degree, came at the same time into the domain of the psychologist and clinician. From a pathological standpoint there was often no apparent cause for the condition of anxiety. The patient was anxious in spite of himself without knowing why. The painful sensation sometimes occurred suddenly in all its force, while at others it took the form of persistent discomfort which lasted throughout life. The acute attacks generally took place during the night or toward morning. The form of continuous discomfort was observed more particularly in certain degenerates, who expressed this condition by an habitual pessimistic view of life. They doubted everything, even themselves, and lived in perpetual anticipation of misfortunes which happily for them never happened. So anxiety flourished in neuropsycopatic soil, sometimes in the form of a neurosis, sometimes in the form of a psychosis. The states of anxiety were for a long time confused with the emotional maladies, but it was finally recognized that at the foundation of emotional conditions there were always anxiety or anguish. It was, however, especially in recent years that, in the study of certain states, related at the same time to both neuroses and psychoses, anxiety had been isolated from the general group of the emotions and has been assigned its true status. The question of the anxious states or conditions in mental maladies has reduced itself to a great degree to the semeiology of anxiety. As to the history of this subject, Cérise (1843 and 1872), Morel (1853 and 1866), and Guislain clearly described the anxious states under the term of emotional delirium. Raymond and Janet devoted a chapter in their work "Neuroses et idées fixes" to this subject. Flemming, in 1848, called attention to præcordial pain as one of the most important symptoms of insanity, and he declared that the symptom was due to an affection of the pneumogastric. Kaan, Hecker, and Freud have written on the neurosis of anguish. In 1897 Pitres and Régis demonstrated the leading rôle of anxiety in the genesis of pathological obsessions. For the clinician anxiety presented itself under the form of discomforts due to a great number of troubles which attack the entire organism and are concerned with all of its functions. As to the symptomatology, whether the affection existed in its lightest or most severe form, anxiety was an emotion which possessed the entire being in its physical, emotional, and intellectual functions. The first group, *i. e.* the physical symptoms included among the troubles of general sensibility, the anæsthesias, which explained certain automutilations, the hyperæsthesias, and the paræsthesias. In the domain of the special senses were often noted the perversions, such as chills of the scalp, horripilation, hyperosmia, hyperacusis, photopsia, and chronopsia. These perversions might reach the point of illusion and hallucination. The motor troubles that were noted in the anxious states were asthenia, general lassitude, and sometimes contraction of the respiratory muscles; the flexors might be so contracted that the body was curved in a movement of defense; there might be a relaxing of the masseters and of the vesical and rectal sphincters; there were also nervous cough with spasm of the larynx, diminution of the patellar reflexes with hypotonia, tremor. according to the degree of emotion, incoordination of voluntary movements far more apparent than real, emotional troubles of elocution, and vertigo which was dependent upon vasomotor cerebral troubles or upon digestive troubles. In the anxious states there were always circulatory troubles, such as rapid heart beat, irregular contractions of the organ, peripheral vasoconstriction, increased arterial tension, pallor and flushing of the face, and coldness of the extremities. Besides these disturbances there were observed respiratory troubles, characterized by acceleration of respiration, modification of the rhythm, even to the point of dyspnœa, jerky inspiration, and sighing. Again, the digestive troubles included constipation, gastrointestinal atony, crises of diarrhœa, and a variety of gastric pains. Among the secretory troubles were noted often, polyuria, sometimes retention of urine, salivation, or, on the contrary, extreme dryness of the mouth, general or local hyperhidrosis, or, on the other hand, abnormal dryness of the skin. In the group of emotional and intellectual symptoms were observed anxious attention with permanent fear of painful events; secondary to this attention, the obsessions and the feelings of dread or apprehension (Pitres and Régis); diminution of the faculties of attention, of volition, of memory, of the association of ideas, of judgment, a diminution determined by the power of disassociation which all of the emotional states possess; sometimes the arrest and in other cases rapid development of mental representations; the projection, under hallucinatory form, of very intense mental images; finally, as a sequel of sensorial troubles, the perversion of the faculty of perception, which might end in the alteration of the personality (Ribot). The writer next considered the subject of anxiety outside of psychopathies. First physiological anxiety was observed in normal individuals, in certain circumstances of life—for example, examinations, competitions, or appearance on the stage. Again anxiety in the somatic maladies was found in abdominal typhus, cholera, yellow fever, and leprosy; in poisoning by serpent venom, nicotine, opium, or carbonic oxide; intestinal hemorrhages; maladies of the heart, such as true angina pectoris, or that which is due to neuralgia of the cardiac plexus or even to a spasm of the arteries; hysteria, neurasthenia, and epilepsy. The third section in this group were the neuroses of anguish. Under this term Kaan, Hecker, and Freud included a group of symptoms, which they separated from the neurasthenia of Beard, to make of it a special morbid type, in which were found the following signs of general irritability with auditory hyperæsthesia, anxious attention, acute anguish or its equivalents, insomnia, night terrors, vertigo analogous to that which occurs in paralysis of the eye muscles, dread, and obsessions. The etiology of the neurosis of anguish was chiefly of the sexual order (Freud); other factors might also play a part, such as overexertion, preoccupations, and night watching. Grave hereditary taints were often determined. But Pitres and Régis did not think that the neurosis of anguish represented a special malady, and this opinion seemed to be held by the majority of authorities.

Anxious Psycopathies.—Under this section the speaker grouped certain forms of insanity in which as he stated the leading symptom during the period of development was anguish in its different aspects, whatever might be the form of the delirium The clinical symptoms which characterized the psychoses of anguish he summed up as follows: A common basis of pre-existent anxiety, troubles of sensibility, analgesias and hyperalgesias of various kinds, functional alterations of muscular sense which might be the origin of certain troubles of personality, troubles of visceral sensibility, loss of the faculty of mental representations, occurred frequently in these patients and determined in them the ideas of negation (Cotard); often intermittent hallucinations, which were sometimes visual, sometimes auditory, sometimes motor verbal, sometimes genital, especially in the psychoses of anguish with ideas of possession, and in certain organic cases (Tamburini), constituent of the false sensations due to aberrations of visceral consciousness; delirium made up of ideas of melancholic nature; fears, frights, terrors, hypochondriacal preoccupations, ideas related to possession, damnation, and negation. The reaction, he declared assumed different forms. Sometimes it was that of annihilation, and sometimes it was that of exaltation with great motor agitation. The transition term between simple melancholy without delirium and anxious melancholy had been suggested by Krafft-Ebing as melancholy with præcordial anguish; that is, crises of paroxysmal anguish, occurring chiefly in the morning during the course of a melancholy without delirium. Anxious melancholy, the speaker said, was par excellence the psychosis of anguish. An acute and a chronic form had been noted. Chronic anxious melancholy showed a systematic progress, recalling the evolution of the delirium of persecutions of Lesègue. Several phases had been observed. A phase of primary melancholy, a period of doubt (Vallon), described by Lesègue as perplexed melancholy (Ritti); a melancholic delirium with ideas of negations, of damnation, of possession, with an entire alteration of personality; a phase of megalomania, variable megalomelancholy, according to the expression of Régis, and to which Cotard had given the name of the delirium of enormity. Although the delirium of negations might have a grave prognosis, the malady was, nevertheless, not incurable.

As to the psychoses of progressive obsession, according to the report of Falret to the Congress of 1889, it had been admitted that the obsessions were not transformed into insanity. Since that time, Pitres and Régis, Wille, Mercklin, and Sommer, had demonstrated that insanity could be the result of the transformation of progressive possession. The psychopathic forms were the anxious melancholy and the rudimentary paranoia, or systematized reasoning delirium. Besides these conditions, which had just been described, and which on account of the predominating rôle that anguish played, deserved to be called the anxious psycopathies, there were others in which anxiety was an important symptom. These conditions were far more frequent than was generally supposed, and, indeed, it might be admitted that every psychosis began with anxiety. The mental forms, in which anguish showed itself the most often, were: The insanity of degenerates, the obsessions and impulses, mania, melancholia, insanity of double form, melancholy of persecution, psychoses of intoxication, neuropathic mental troubles, and general paralysis. The clinical forms of the psychosis of anguish were the transitory anxious melancholy, anxious melancholy, and the psychoses of progressive obsession.

Etiology: It was very frequent, especially among degenerates. The predisposing causes were sex, the anxious states being found most frequently among women. Age seemed to have an important influence, the affection occurring most frequently between the ages of twenty and thirty years. There was a form of morbid fear, that was observed in infancy and adolescence; also a neurosis of anguish, seen in middle age; and also a form seen in old age. Heredity played a most important part in the etiology. The pathogeny of anxiety, like that of the emotions, was still enveloped in obscurity. The first students of this question believed that the origin was in the gray matter of the brain, but the majority now, on account of the marked localization of the phenomena in the cardiac region, had built up a cardiac theory of anxiety. Without denying the importance of the vasomotor troubles in the genesis of the emotions, the speaker believed, together with James and Lange, that in recent years too great a value has been attributed to this point to the detriment of the entire sympathetic system. It was this last, according to Lobstein, Cabanis, Bichat, Cerise, and Morel, which presided over the emotions. The sympathetic theory seemed to be equally adopted by Pitres and Régis. It sufficiently explained all of the cases.

The symptomatology was sufficiently characteristic not to lead to any confusion in the diagnosis. The prognosis of the anxious states might be grave, according to the following conditions: Its tendency to persist; the possibility of secondary morbid forms as obsessions and dread; and possible alteration of personality.

The prophylaxis, according to Marro, consisted in cold hydrotherapy, physical exercises, and education. The patient should be made to accustom himself to consider the objects which frightened him. Among the medicinal means which were suitable to employ in this affection were: Nitrite of amyl, used by Meynert and Krafft-Ebing; trinitrine, recommended by Paoli; opium, in all of its forms; bromide of potassium; chloral, and the cardiac drugs. Treatment by rest in bed was also productive of equally good results.

Arnaud said that he did not think that anguish was exclusively a phenomenon of peripheral organic nature, in which the brain had only a passive rôle. Roubinovitch stated that he agreed entirely with the view of Lalanne that the importance of the intoxications in the production of the anxious states was far greater than was generally considered. In support of this view, he cited several cases. In those predisposed to psychical troubles, this factor of intoxication may be a very important one in the genesis of the syndrome of anxiety. This theory, he added, was of great practical importance in respect to the rational and curative treatment of this condition.

Hartemberg made a clear cut distinction between the neurosis of anguish and neurasthenia associated with anxiety and hysteria. He stated that the neurosis of anguish was characterized by the following symptoms: Extreme general nervous excitement; a condition of chronic anguish or anxious attention; acute paroxysmal attacks of anguish with dyspnœa; palpitations and profuse sweats; equivalents of the crises of anguish and rudimentary crises, as cardiac, respiratory and digestive troubles; obsessions. Of all these symptoms the most constant and the most significant is that of anguish. The functional disorders he believed to be more or less variable. The speaker then quoted cases of this nature in which there were none of the stigmata of hysteria or neurasthenia to be found.

Regis remarked that the place in nosography which neurosis of anguish ought to occupy was not yet definitely defined. The neurosis of anguish, he believed, was only a transition between neurasthenia with anxiety and anxious melancholy.

Giraud remarked that to him it seemed that hallucinations in the anxious states of melancholics held a far more important place than had been assigned to them by Lalanne.

Ballet said that he did not consider this neurosis as a true clinical entity.

Doutrebende expressed himself as a little surprised that Lalanne should recommend cold hydrotherapy in the anxious states. For if, in a healthy individual, one wished to arouse a feeling of anxiety, he had only to give him a douche.

Parent declared that in mental maladies anxiety could assume several different forms. There were those patients who were anxious without knowing why; there were others whose hallucinations provoked anxiety; there were still a third group, in which it was called forth by a delirious interpretation of real facts, as when a man who has been condemned to die believes when he hears a door open that the executor has come for him. As to the treatment of these states, the speaker insisted on the use of opium. He preferred it in the form of laudanum, and the doses could be progressively increased. He had a patient who could take ninety drops.

Briand and Marie advocated bromide as an excellent medicinal remedy in this affection.

Lalanne replied to Doutrebende that he also did not care for the use of cold water in cases of insanity, but circumstances in a clinic sometimes made it necessary to resort to it.

Tics in General.—Nogues read an instructive paper on this subject. He said that under the term tic there had been grouped a number of dissimilar conditions. Our elders did not describe the muscular symptom which we have designated to-day as tic; nevertheless, there was a very rich bibliography on this subject. He recalled the masterly description of Trousseau, the works of Charcot and his students, of Gilles de la Tourrette, Brissaud, Magnan, Pitres and Grasset, Ballet, Meige and Feindel. These last two writers, from the inspiration of Brissaud, have more clearly defined this term, and in their book have presented a series of clinical studies which the speaker declared to be a veritable treatise on tics. Brissaud in his work on this subject, made an epoch in the history of tics and clearly separated tics from spasms. A definite terminology was both necessary and indispensable in dealing with this subject. Although it was impossible to give in certain words the precise definition of tic, the limits of the term could be settled. The most common point of confusion, the speaker stated, was between the terms "tic" and "spasm." Between these two there existed a great difference. Spasm he defined as a motor reaction resulting from the irritation of any point whatever of the spinal or bulbo-spinal reflex axis, the irritation being produced by a pathological cause. Tic he defined as an involuntary movement reproducing a functional act, and having a cortical origin. He quoted Meige and Feindel, who said that in the presence of motor reaction, in which the cerebral cortex did not and never had taken part, there did not exist the phenomenon known as tic. And if this motor reaction was the result of the pathological irritation of any point whatsoever of the bulbo-spinal reflex axis, the phenomenon was a spasm. On the other hand, in the presence of a motor reaction in which the cerebral cortex either had at that time or previously taken a part, then there was not what was called a spasm. And if this motor phenomenon in which the participation of the cerebral cortex had at any time been noted, presented besides certain distinctive pathological characteristics, then it was known as a tic. It was necessary to eliminate from the nosological outline of tics those clonic manifestations following in the wake of the neuralgias. The term of tic douloureux of the face, for example, was a bad one, for it dealt with a spasm and not with a tic, having for its cause a peripheral irritation. Again, certain movements, and certain gestures frequently repeated, should be separated from tic as they were in reality only habit. They were not spontaneous and they were easily overcome by the exercise of a little will power.

Finally, tic was always accompanied by mental phenomena. This fact has been misunderstood, even up to recent years, but has been carefuly studied of late. Magnan and his school determined in a definite fashion the rôle of the psychical phenomena in the production of tics. Their interpretation of this subject has largely contributed to give a conception of tic which conformed with the results of observation. It also had its dangers, for if it were true that an individual could not be afflicted with tic without being a degenerate to a greater or less degree, the converse did not hold true, that is, all degenerates were not afflicted with tic. It is not difficult now to see why all attempts to give a definition of tic have provoked justifiable criticism. A definition ought to be precise, brief, and clear; but the syndrome tic with its double somatic and psychical manifestations has not lent itself happily to a definition always a little arbitrary. Although a great importance might be accorded to the mental condition of an individual afflicted with tic, still the term tic could not be applied to a malady purely mental in which the objective signs, the movements, did not exist. Tic, in fact, was characterized by muscular contraction, brusque, rapid and instantaneous. The general characteristics of tic were enumerated as follows: The movements were voluntary, habitual, alternately conscious and unconscious, coordinated, systematic; they were the motor perturbations of functional acts. Ordinary tic was clonic, but there existed tonic tics, of which the prototype was the mental torticollis of Brissaud. But to make these points clearer, tic was really a voluntary movement in the beginning, which, little by little, had become automatic, but which could be suspended by inhibition. It should be added that this action of volition was difficult to exercise, for it was precisely this inhibitory power of volition that was diminished in the individual afflicted with tic.

The second characteristic of tic, that of being habitual, could not be denied. Tic differed, nevertheless, from habit movements as has been noted, in that an effort to hold the attention suppressed the tic, while the habit movement was more apt to manifest itself when the attention was concentrated on that point. As to the consciousness of the afflicted individual, there have been many controversies. It could probably be explained by the fact that the individual was conscious before and after the movement, but not during its performance. Coordination was one of the clinical characteristics which distinguished tics from spasms. The tic was coordinated, systematic, and adapted to an end. The apparent muscular paresis in these patients was only the inability to execute certain movements which were commanded. The muscular contractions did not succeed each other in tic with a certain rhythm and at almost equal intervals; the speaker said that it did not seem to him that those movements described under the name of rhythmic tics or rhythmic spasms could be ranged in the same category as tics. In the greater number of cases several muscles took part in the movement of tics. Tic could be located in various parts of the body. In other words, the variety of tics was infinite, and it was almost impossible to describe all of them. Every patient could create a new one each day. Their number was as unlimited as the functional acts of which Charcot called them the caricature. They could be designated by the part in which they were located, and by the functional act of which they were a perturbation. Tics were observed most often on one side of the body, although two symmetrical muscles might be attacked. The motor reaction of tic could also be exercised over two antagonistic muscles, from which there resulted immobility of a member, or part, in the attitude of determination. There were frequently observed in the same individual several simultaneous tics and dissimilar movements, which succeeded eath other at very short intervals. Tics might be classified according to their location in the body, as follows:

(1) Tics of the face. The face was the most frequent seat of tics; mimic tics. In the eyes were the tics of nictation (batting of the eyelids, winking). In the mouth were seen the tics of the lips (tics of suction, mimic tics), and those of the tongue (tics of licking, of chewing, of smacking, of whistling, and of croaking). The most frequent tic of the nose was snuffling. In the jaw were observed the tics of nibbling and of mumbling, as well as the biting of the lips and of the nails. (2) Next in frequency to the face as the seat of tics, came the neck. Tics of shaking, of approbation, affirmation, salutation, negation, and mental torticollis. This last is a tic alternately clonic and tonic. (3) Tics of the upper extremities were less frequent than the preceding, and rarely occurred as isolated movements, but were associated with those of the head or neck. In the arm could be noted the tic of raising the shoulders; the tic of scraping with the hands. (4) In the trunk might be seen the movements of salutation, and of balancing. (5) In the lower limbs have been observed the tics of genuflection, and of jumping. Finally there were the tics which were merely the perturbations of organic functions—deglutition, digestion, and respiration. All of these tics had the general characteristics which have already been studied. They were also accompanied by variable accessory symptoms—reflex troubles, vasomotor or secretory troubles, and troubles of sensibility.

The theories and discussions concerning the real nature of tic had been varied and numerous. Unquestionably, the leading symptom of tic was the mental state. Charcot said that tic was a malady which was material only in appearance; it was from one point of view a psychical malady, a direct product of insanity. The writer added that this was the general belief, but the point difficult to determine was the precise mental condition of these patients. There had to be a special mental condition before this affection could occur. The patient was psychically unbalanced. The speaker did not agree with Meige and Feindel, who wished to add to these cases another mental anomaly, which they regarded as characteristic and pathognomonic; namely, the infantile mental state. It could not be denied that those suffering with tic had certain psychical characteristics of the child; for example, versatility, aboulia, and impulsiveness. They might be designated as a superior order of degenerates. They were unbalanced. In the study of these patients, a noticeable fact was not so much the insufficient development as the unequal development of their faculties. Magnan's idea concerning their mental weakness seemed too comprehensive for these patients, for, aside from certain psychical anomalies, they often possessed intellectual qualities of the first order. They seemed impelled to do not only just the contrary to what they were told, but even the contrary to what they thought themselves, and wished to do. The mental infantilism of these patients should not be given too important a place, but their psychical condition should be regarded as that of the degenerate, especially of the superior degenerate, and of the mentally unbalanced. Their feebleness of volition was manifested by extreme voluntary inability. The least difficulty confused them, and they were incapable of making the effort to surmount an obstacle. The power of attention was diminished. These patients often showed movements of impatience and expressed haste in many of their actions. They fatigued themselves by continual agitation. Their sympathies and antipathies were extreme and unreasonable. Their mental state was often complicated by fixed ideas and obsessions. They were often possessed by sudden desires, and imperious caprices. They were very variable and had no perseverance. It might be said that their mental trouble was a malady not of the will, but of the emotion. Tic and obsessions were frequently encountered in the same family, and they might even be associated in the same individual. In such a case tic gave birth to obsession or obsession gave birth to tic. The analogy between tic and obsession could not be applied to all kinds of obsession, but only to the impulsive obsessions; that is, obsessions with a motor tendency. Finally, the two elements constituting tic were stated to be the motor phenomenon and the mental trouble. They were subordinate one to the other, and really constituted the syndrome which was designated by the term tic. Tic was a psychomotor trouble. There existed almost always a cause for the movements which constituted tic, although it might not be easy to depict it at times. The infectious maladies, the intoxications, the emotions, the traumatisms, the manner of life, and irritation could provoke the development of those troubles. Tics could appear in the course of hysteria, although they were not of an hysterical nature. There could be a coexistence, but independence of the two maladies. The same was true of neurasthenia. Diagnosis was to be made between tic and spasm, according to the differential points mentioned before. But of all maladies, it was Sydenham's chorea that showed the most striking analogy to tic. Nevertheless, in chorea there was no coordination; the movements were not similar; they were irregular, illogical, absurd, very rapid, succeeding each other almost without interruption. The contractions passed from one group of muscles to another, and volition had no power. Tics did not present a regular evolution. It could be said in a general way, however, that the beginning was insidious. The first movement was a gesture, which finally became a habit. The causes were diverse. Soon the cause disappeared, but the convulsive movement remained and tic was established. From this point its evolution assumed different forms. Sometimes it was continuous; sometimes it was suddenly arrested under the influence of some distraction, of absolute rest, of some emotion, or of some illness. It must be added that the same causes under certain circumstances could cause the reappearance or the exaggeration of tics.

The course of this affection was invariably long, but it was not incurable. In fact, there was frequently a favorable termination, in the sense that an amelioration or even a cure could be looked for if treatment were persistently kept up. The chances of cure depended, to a certain extent, upon the age of the patient and upon the length of time that the disease had existed.

From the nature of this disease, the treatment was of two kinds; the one part was directed to the motor phenomena, and could be called objective; while the other was directed to the mental condition' and was designated by the terms psychical or subjective. Both methods could be subdivided into several groups. Under the objective treatment, medicinal measures were first considered. They comprised bromide, opium, valerian, injections of morphine, of curare, of atropine, and inhalations of chloroform and ether. Of course there was always the danger of establishing the drug habit. Under hygienic treatment the diet deserves an important place. Hydrotherapy was sometimes useful, although sea-baths were not advised. Massage was sometimes useful, as was also electrotherapy. Rest in bed was recommended. Surgical measures were sometimes employed, such as the division of tendons and nerve stetching. The latter caused a temporary paralysis which was overcome by making the patient perform certain muscular movements.

Various authorities had suggested different methods of treatment. For example, Brissaud, Meige, and Feindel advocated perfect immobility for a certain period, after which the patient was told to execute certain movements. This plan had met with excellent results. Dubois advocated verbal suggestion in the waking state, which assisted the patient to hold himself immovable. Pitres had the patient stand upright with his back against a wall, his heels together, and his arms close to his hips. During two or three minutes he recited a fable, making slow and deep respirations. These exercises were repeated every few hours, and the duration was gradually increased until it reached perhaps twenty minutes. Then these performances were reversed, the length of the seances having been as gradually decreased as they had been formerly increased until finally they ceased altogether. It should have been stated that for several minutes following the repetition of the verses the patient was made to breathe very slowly and deeply, gently raising the arms during inspiration, and lowering them during expiration. Meige and Feindel suggested having the patient practice before a mirror, where his mistakes would be constantly called to his attention.

As to the subjective treatment, hypnotic suggestion was rarely employed, as it tended to diminish volition. On the other hand, however, waking suggestions had produced excellent results. Isolation was not advised for every patient, but when it was used, it should be under the charge of the physician or some one of authority. When the family did not understand the gravity of the affection, the patient should be removed to an institution. In using psychotherapy, the physician constituted himself the teacher.

Auto-Accusors from the Medicolegal Point of View.—Dupré delivered this discourse. He said that this was a subject rich in literature for the physician, the psychologist, and the lawyer. From the point of view of clinical psychiatry, the term auto-accusor was applied not only to the individual who declared that he had committed a crime, the details of which he related of the time, the place, the circumstances, and the execution of it, but it also applied to the individual who possessed an unfavorable judgment of himself, who constantly depreciated himself, who spoke of his physical and moral inferiority, and expressed ideas of his incapacity, his unworthiness, his guilt, and his remorse. But, in the language of medicolegal psychiatry, this term had a narrower significance, and applied only to the person who, delirious or lucid, sincere or insincere, possessed of hallucinations or reasonable, moved by a pathological sentiment of self-denunciation or by a motive of self-interest, accused himself of an act, provoked or spontaneous, direct or indirect, verbal or written, against the administrative or judicial authorities. In legal medicine, auto-accusation was then a synonym of auto-denunciation. Self-accusation in melancholics proceeded directly from psychical inhibition and moral pain, which made up the pathogenic substratum of delirious melancholy. That delirium, which first assumed the form of ideas of general guilt could by means of automatic processes, of logical inference and reasoning deduction, develop into a delirium of definite guilt, which presented clearly to the consciousness a definite sin. The elements which determined with such precision the crime under consideration might be due to the morbid interpretation of external occurrences, or to the remembrance or exaggeration of slight past faults, or to a fixed idea derived from a dream, or to the personal attribution, direct or indirect, of misfortunes, catastrophies, or crimes, of which the melancholic assumed the responsibility. The greater number of auto-accusors did not pass the delirious stage, in which, by a variable mechanism, the idea of definite guilt had taken shape. These patients remained then platonic in their ideas of auto-accusation. Some of them went still farther and passed from the idea to the act. From auto-accusors they developed into self-denunciators. This logical evolution of the melancholic from the idea of indefinite guilt to that of definite guilt or auto-accusation, and from the platonac idea of auto-accusation to the act of auto-denunciation, recalled, in a certain sense, the medicolegal evolution of the patient afflicted with the idea of persecution, who also passed from the condition of vague ideas of persecution through the various stages till he reached that of active vengeance. In both cases the patient passed from the clinical domain to the medicolegal, and this evolution was marked by a social act, which was the logical result of his belief. The several stages of the evolution of the melancholy delirium of auto accusation were enumerated as follows: (1) State of melancholy; (2) Delirium of indefinite guilt; (3) Definite auto-accusation, but passive and platonic; (4) Active auto-denunciation. Nearly all melancholics reached the second stage; many reached the third; but very few reached the fourth. Those alone were the medicolegal melancholic auto-accusors. Nearly all of these patsient were women, and the greater part accused themselves of crimes, especially of infanticides. Auto-accusation in degenerates was extremely frequent. It was encountered in debility and in unbalanced mental conditions, in the course of obsessions, and in the different varieties of degenerative paranoias. The inferior degenerates constituted a very special category, rich in types which were varied and curious. Each one constituted himself the hero of the crime which he pictured. He was troublesome to the magistrate, often puzzling to the psychologist, and always interesting to the physician. Contrary to the melancholy auto-accusors, who were delirious, sincere, anxious, and repentant, the degenerate auto-accusors were nearly always lucid, conscious, insincere, indifferent, or vainglorious. Contrary to the melancholics who had all, in the uniformity of their delirium, a familiar air, the degenerates were all different from one another, and showed the most variable and the most individual clinical physiognomy. Each case was one by itself. Several types could be distinguished among the degenerate auto-accusors: (1) The simple intellectually feeble, who denounced themselves from the influence merely of an impulsive suggestion, following a conversation, a dream, or something they had read; this was auto-accusation by elementary psychical reflex, without any mental associations. (2) The vain, intellectually feeble, who denounced themselves from a desire for glory and from a wish to be talked about. (3) The morally weak, egotists, with perverted instincts, who placed at the service of their bad appetites the premeditated act of auto-denunciation. (4) Those possessed by the ideas of obsession, who were doubtful and anxious, and asked themselves if they had actually committed the crime, the idea of which they had nursed until they really believed themselves guilty. (5) The paranoiac degenerates, who formulated the ideas of auto-accusation, were the primary systematic auto-accusors (Séglas) and the persecuted auto-accusors, studied by Ballet, Séglas, Lalanne, in whom were associated the two deliriums of persecution and auto-accusation. Likewise the states of melancholy, hypochondriasis and obsession, complicated the psychopathic process under consideration. (6) The delirious auto-accusors could interest the legal physician by their attempts at suicide and their tendency to auto-mutilations, and to the obstinate pursuit of surgical intervention. Aside from these phases, these delirious, degenerate auto-accusors had no medicolegal interest. Among the degenerate auto-accusors, especially among alcoholics with ideas of persecution, the feeble-minded, and the unbalanced, the most diverse morbid associations, such as alcoholism, hysteria, epilepsy, and infections, could come in as etiological factors. The most frequent was alcoholism. This factor incited the patient to the act of self-denunciation by exciting the psychological automatism and by weakening the power of inhibition. Auto-accusation in alcoholics presented, on account of its frequency, its pathogenic mechanism, and its clinical evolution, the greatest interest. There were observed, always in adult men, under the influence of alcohol, and who had been so for some time, episodic elements added to the chronic alcoholism. Auto-accusation was one of the delirious forms of psychical drunkenness, observed among those predisposed, and among imaginative individuals. In his mental confusion, the patient became convinced that he had committed a crime, bloody in nature, the details of which were borrowed from the circumstances of his daily life. The idea was always ephemeral, and remained only a few hours, having passed through various phases. Auto-accusation of toxic psychoses was observed equally in typhoid patients, in the states of inanition, and in certain crises of indefinite etiology, but certainly of toxic nature. This transitory patient ought almost never to be placed in an asylum. A short period would be sufficient to determine the nature of the malady. Auto-accusation in hysterics was extremely rare in comparison with hetero-accusation. Sometimes there was a combination of auto-hetero-accusation of a sexual nature. As to the situation between the auto-accusor and the author [illegible] Régis had submitted a simple classification. The individual accused himself of. (1) A crime that did not exist. (2) A real crime, but not imputable to the auto-accusor. (3) A real crime, imputable to the auto-accusor. (4) A real crime committed by him, but exaggerated by the deposition, or caused by the solicitation, under pathological influences, generally of the impulsive order; sometimes under the influence of remorse. Every auto-accusation presented a double problem: One, judicial, for the magistrate, and the other, medical, for the expert. The first problem, the demonstration of the reality or of the imputability of the crime, nearly always preceded the other, the demonstration of the insanity of the auto-accusor. There were interesting differences in the penal code of foreign countries. The expert had the problem to solve of the diagnosis of the mental state of the auto-accusor, which required the thorough examination of the auto-accusor, and of the accusation. This should be studied from all points of view, its etiology, its pathogenic mechanism, its clinical aspect, the steps in its evolution, and its psychical and somatic concomitants. It was by the aid of all these elements that the expert could determine the pathological type of the accusor. The reality even of the crimes revealed by the auto-accusor did not militate against the possibility of the morbid nature of the auto-accusation (Régis). Auto-accusors were derived in order of their frequency first from among alcoholics, then from degenerates, and far fewer than those in these two categories were those in melancholy and hysterical states, and finally those in the conditions of dementia. Different processes often combined in the etiology of auto-accusation. About two-thirds of auto-accusations had to do with crimes of which the non-existence and the imaginary nature were established by a short inquiry. The other third had to do with real crimes committed and avowed by those guilty of them, but under pathological influences. Many regrettable consequences followed in the train of this subject of auto-accusation, and were of importance enough to justify the medicolegal clinical study of the auto-accusor. This report was warmly praised and discussed by various members of the congress.

Following these papers came short communications on various subjects. Piqué and Marie spoke of the relations between traumatism and insanity. Traumatism, they said, was often the cause of insanity. The acute psychoses immediately consecutive to traumatism were often cured.

The necessity for disencumbering the asylums was mentioned by Doutrebante.

Marie and Duflos reported on lumbar puncture in general paralysis. The number of lymphocytes varied in different cases.

Lumbar Puncture in the Diagnosis of General Paralysis.—Joffroy and Mercier presented a communication on this topic. In a great number of these cases diagnosis was impossible by the old methods of investigation, but could be made by the lumbar puncture. In many cases determination of numerous white elements in the cerebrospinal liquid confirmed the diagnosis, while their absence permitted the rejection of the diagnosis. This method showed the difference between general paralysis and various forms of alcoholism; it also differentiated general paralysis from the beginning of a psychosis, and from certain curable attacks of mania or melancholia. In fact, the presence of numerous white elements in the cerebrospinal liquid was the most constant and the earliest of the physical signs of general paralysis.

The Convalescent Insane. Larrivé read a paper with this title. He believed it to be an excellent plan to give convalescent patients short tentative leaves of absence from the asylum. They then grew gradually and comfortably reaccustomed to ordinary life, and did not feel so embarrassed on their return home after their confinement. He believed the establishment of convalescent quarters necessary.

The Aboulia of Chronic Alcoholics.—Bérillon offered some remarks on the treatment of these cases by hypnotic suggestion. The application of the treatment must be rigorous to insure success. There should be psychological examination of the subject and of his individual character. The absolute consent of the patient must be obtained. The aptitude for being hypnotized must be developed. There should be gradual diminution of alcohol, and finally complete suppression. The convalescence was from two to six months. When the method was faithfully followed out, cure was obtained in the majority of cases.

General Paralysis in Brothers.—Joffroy and Rabaud reported the case of two brothers afflicted with general paralysis, belonging to a family of degenerates. Autopsy confirmed the clinical diagnosis. The maternal grandfather had been an alcoholic, and had died insane. These men died of the same malady, although they had been subjected to dissimilar influences.

Glioma of the Nerve Centers.—Oberthür presented a contribution on this subject. He had been enabled to examine seven cases of this nature in the laboratory. Macroscopically, the appearance of glioma was sufficiently characteristic to differentiate it from all other tumors. It was always clearly translucent, except in the degenerated parts; the color was rose, or yellowish gray; its consistence often very diffluent, even gelatinous; it was never encephaloid. A great number of small vessels coursed through it, giving place at times to central hemorrhagic suffusions. Although the tumor could never be enucleated, it was sometimes limited by a pseudo-wall of dense neuroglia. Outside of this wall the infiltrated gliosis was like that which surrounded all foreign bodies in the brain, not having the aspect of a neoplasm. In one case which had existed for three years, the only symptoms were headache with optic neuritis and amaurosis, permitting no localization. Other cases had a more destructive course.

Malignant Disease of the Nervous System.—Philippe, Cestan, and Oberthür presented a study of fifteen cases of sarcoma of the nervous system. They divided the cases into those of solitary sarcoma and of multiple sarcomata or sarcomatosis. The power of generalization of the latter was very great, as the tumors sometimes invaded the entire nervous system, central and peripheral, like a true neoplasm. Two forms of multiple sarcomata were noted—the meningitic form, and the form of neurofibrosarcomatosis.

Oberthür also presented a contribution to the study of cancerous localizations in the peripheral nervous system. The lesions were sometimes neurites and toxic or autotoxic polyneurites, while they were sometimes due to compression and invasion.

Cerebellar Atrophy.—Lannois and Paviot spoke of the histological lesions of the cortex in atrophies of the cerebellum. They reported several cases.

Faure and Laignel-Lavastine reported laboratory work concerning the histological study of the cerebral cortex in eighteen cases of meningitis. They spoke of the interstitial and of the cellular lesions.

Keraval and Raviart made some communications on the "condition of the fundus of the eye in general paralytics" and the initial lesions. They spoke of the alterations in the retina, the optic papilla, and in the optic nerve.

Durante made a contribution to the "histological processes of muscular atrophy." All of the amyotrophies revealed the same histological processes and differed only in the distribution of the lesions and in the rapidity of their evolution.

Larrivé spoke of the treatment and assistance of abnormal children He advocated the establishment of asylum schools.

Obregia made a few remarks on the innervation of the vessels of the pia mater and of the cerebral cortex.

Reflexes.—Crocq discussed the subject of the mechanism of the reflexes and of muscular tonus. He said that muscular tonus was exclusively cortical, while reflexes were of three classes—medullary, basilar, and cortical. In speaking of the catatonic symptom, he said that the important question was to learn whether catatony was due to nutritive troubles or whether the converse were true.

Pailhas made a few remarks on the lasting or prolonged extension of the great toe associated with Babinski's sign. He had observed four cases of this kind.

Cestan and Dupuy-Dutemps discussed the Argyll-Robertson pupil. They advised the use of cocaine for the examination of contracted pupils.

Pailhas spoke of the involuntary abduction of the little finger and troubles of speech. He had noticed the association of these two abnormalities.

Alcoholism.—Bonnet described his treatment for alcoholic addiction. He believed in milk diet and lactose; sometimes theobromine, the purgatives, and even injections of serum.

Legrain and Guiard spoke of relapses in chronic alcoholism. They said this was a moral and social work. The alcoholic should be treated early.

Ducosté spoke on neurasthenics and neurasthenia. He thought that "neurasthenic states" were only the symptoms of different effections or maladies caused by a defective nutrition of the cerebral cells. Constitutional neurasthenia was more than a symptom; it was a true clinical entity.

Faure made some remarks on the origin of tabes. He thought that the cases ought to be very carefully studied as to their differences of origin, so that they could be properly treated. He described, in a second paper by himself and Constensoux, the advantages and limitations of massage in tabetics.

Meige discoursed on the correction of tics by the control of mirrors.

Hartenberg reported two cases of paramyoclonus multiplex.

Meige offered a few remarks on the marriage of giants. These individuals were subject to various defects, and when married to one of the same kind tended to perpetuate the same.

General Paralytics in the Courts.—Maxwell concluded the congress with a paper on the treatment of the subjects of incipient general paralysis by magistrates. He said that the physician should always be consulted in these cases. The subjects were ordinarily more dangerous to themselves and their neighbors than they were to the community at large. They were not habitually impulsive, committing flagrant crimes. Murders were rare among them. But less serious crimes, such as public outrages to modesty, abuse of confidence, etc., were common. The patient was often, when summoned to court, found to be between twenty-five and fifty years old, and had always before borne an excellent reputation. Suddenly he had committed some immoral punishable act. The proofs of his guilt were not even hidden. His attitude was often indifferent. Great care should be observed in the disposal of such cases in persons who, after having lived for years in a manner beyond criticism, were suddenly arraigned in court. It would be well to formulate a few rules, so that the magistrate could have some idea of the case he was dealing with from a medical point of view. He should note if the prisoner had been late in manifesting the ideas of ambition and exaggeration; if he had committed the fault without trying to conceal it; if he showed indifference which was difficult to understand in a delinquent arrested for the first time; if he had any troubles of memory, forgetting recent events and remembering earlier ones; if in writing he forgot letters or syllables, or made mistakes in spelling; if he made gross errors in calculation; if his conception of abstract ideas was intact. The speaker thought that a little manual should be prepared which would present the views of the principal alienists in regarding the legal relations of these unfortunates.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 6, 1902:

	Cases.	Deaths.
Measles	44	1
Diphtheria and croup	176	16
Scarlet fever	96	9
Smallpox	12	..
Varicella	3	..
Tuberculosis	190	125
Typhoid fever	210	20
Cerebrospinal meningitis	..	3

Schedule of Minimum Requirements for Medical Colleges Recognized by the Illinois State Board of Health.—The following standard has been adopted by the Illinois State Board of Health, and after January 1, 1903, no college which does not conform to it in every particular will be recognized by the Board as in good standing:

Conditions of Admission to Lecture Courses.—1. Creditable certificates of good moral character signed by two physicians of good standing in the State in which the applicant last resided. 2. As evidence of preliminary education, as a minimum requirement, a diploma or certificate of graduation from a high school; or a certificate signed by a principal of a regularly organized high school, or by the examiner of the faculty of a recognized literary or scientific college or university, or by the State Superintendent of Public Instruction, or a Superintendent of Public Schools, or having successfully passed an examination in all the several branches embraced in the curriculum of a four years' high-school course. The matriculation examination shall be conducted by any member of the faculty of the medical college. The Illinois State Board of Health will require each applicant for a State certificate to present documentary evidence of his preliminary education, together with his medical diploma, when taking the examination of the Board. The conditions above set forth will govern in case of all persons admitted to the Freshman Year of a medical college in "good standing," on or after January 1, 1903.

Advanced Standing.—Applicants holding the degree of A. B. or B. S., or an equivalent degree from a regularly established college of arts or science, which requires an attendance of three or more years as an essential to graduation, may be given credit for work done in the branches of the medical curriculum of the first year and may be advanced to the Sophomore Year of a four years' medical course, on condition that they comply with the entrance requirements of this Board, and that they subsequently complete the work of the Freshman Year if not already completed, and that the work already taken shall not be below the standard required by this Board. The same advanced standing may be allowed on the same conditions to applicants presenting a degree from a recognized college of Dentistry or College of Veterinary Medicine, or documentary evidence of having completed, in a reputable university or college of arts or science, the major part of the work usually embraced in the curriculum of the freshman course of a recognized medical school. No such advanced standing shall be allowed until after the applicant shall have either graduated as indicated or performed the work specified above, and not until three months after the completion of said work. The above requirements for advanced standing will govern in the case of all persons admitted to the Sophomore Year of a medical college on or after January 1, 1903, and may be made operative prior to that time. Graduates of medical colleges, recognized at any time by the Illinois State Board of Health, may be admitted to any class without examination. Students of said colleges who possess certificates of attendance and of successful examinations, can enter without examination the term immediately following that previously attended. The student shall be required to pass an examination in all branches in which he has been found deficient. Students who have attended one or more full terms in colleges not fully recognized by this Board may be granted advanced standing in accordance with such attendance, on complying with the entrance requirements set forth in the conditions of admission to lecture courses, and passing all examinations and performing all laboratory work of the classes below that which they enter, providing that the work already done conforms to the requirements of this Board. Graduates or students of colleges to which no recognition is given by the Illinois State Board of Health can be granted no advanced standing whatever.

Length, Number, and Character of Courses of Lectures.—The college shall have a four years' course of instruction, consisting of four terms, extending over a period of four calendar years, and the minimum time between the commencement of the work of the Freshman Year and the ending of the work of the Senior Year, on which all students are required to be in attendance, shall be not less than forty months. No two terms begun on or after January 1, 1903, shall commence and end within any consecutive sixteen months. The time occupied in each regular term began on or after January, 1, 1902 shall be not less than seven months or thirty weeks, and each such term shall consist of not less than eight hundred hours of work. The branches of medicine to be included in the course of instruction shall be at least as follows: (1) Anatomy; (2) Physiology; (3) Chemistry; (4) Materia Medica and Therapeutics; (5) Theory and Practice of Medicine, including Ophtalmology, Otology, Dermatology and Neurology; (6) Pathology and Bacteriology; (7) Surgery, including Orthopedic Surgery; (8) Obstetrics; (9) Gynecology; (10) Hygiene; (11) Medical Jurisprudence (Forensic Medicine).

Attendance.—Regular attendance during the entire lecture courses shall be required, allowance being made only for absences occasioned by the sickness of the student or his immediate family, such absence not to exceed 20 per centum of the course.

Dissections, Clinics, and Hospital Attendance.—(1) Each student must have dissected at least the lateral half of a human cadaver. 2. He shall have received clinical and hospital instruction throughout at least two annual terms.

Instruction.—The college must have a sufficient and competent corps of instructors, and facilities for teaching, dissections, ambulatory and hospital clinics, such as obtain in the majority of medical colleges in the United States.

Graduation.—No student shall be graduated by any medical college in "good standing" with the Illinois State Board of Health who has not completed four full terms of lectures as prescribed by the rules of the said Board (certain persons to whom advanced standing is allowed excepted) and has complied with the requirements of the said college, as set forth in the published announcement of the college, and has completed in the college by which his diploma is granted a continuous course of lectures in the Senior Year of at least seven months in duration.

Further Conditions of Recognition of Medical Colleges.—1. Only regularly conducted and legally chartered medical colleges which conform to the conditions of admission to lecture courses, the course and period of study, the number, character and length of lecture terms, the duration of attendance on hospital and clinical instruction, as set forth in the Schedule of Minimum Requirements adopted by the Illinois State Board of Health, and the other requirements of a medical education which obtain as the practice of a majority of the established medical colleges in the United States, shall be considered medical institutions in "good standing" according to the purpose of the Act to Regulate the Practice of Medicine in the State of Illinois, approved April 24, 1899. 2. No medical college can be held in "good standing" until it has established its claim to such standing by an active existence of not less than four years, and then only on compliance with the terms of Rule 1. Provided, that colleges which after a personal investigation made by a committee of the Illinois State Board of Health, are shown to comply with the Schedule of Minimum Requirements and to possess a sufficient and competent corps of instructors, and the necessary facilities for teaching may, at the discretion of the Board, be granted full recognition during the first year of existence. 3. All medical colleges in "good standing" with the Illinois State Board of Health will be required to publish in their annual announcements or catalogues a complete list of all matriculates and a separate list of all graduates of the session or year immediately preceding. 4. No medical college will be considered in "good standing" with the Illinois State Board of Health which publishes in its annual announcement or catalogue, or otherwise, any misrepresentations regarding the curriculum of the college or the facilities for instruction, or the number of students matriculated or graduated.

Volvulus Cæci.—R. Faltin enters into an extensive review of this condition, using as the basis of his considerations twenty-six cases observed by him, twenty-five gathered from the general literature and twenty-four which have been separately reported by Manteuffel. The disease is most frequent between the eighteenth and thirtieth years of life. Seventy per cent. of the patients were men. The most prominent predisposing cause is an abnormal movability of the cæcum. This may be brought about by an abnormal position of the retrocæcal connective-tissue, a common ileocæcal mesentery, an ascending mesocolon, and an apparent or real elongation of the cæcum. The volvulus may take place in any one of three different directions, a vertical, a transverse, or a sagittal. The exciting causes may be varied, but are usually traumatism or acute intestinal disturbances, The symptomatology is diversified, and depends upon the amount of small or large intestine which is involved in the volvulus. Vomiting is almost a constant symptom, since it was absent in only five cases. In 20 per cent. of the cases this vomiting was fecal in character. A local meteorism was noticed in thirty-eight cases. The differential diagnosis is principally between this condition and volvulus of the small intestine or sigmoid flexure. A satisfactory differentiation from the former is usually impossible. Volvulus of the sigmoid flexure usually occurs in patients over thirty years of age, is not accompanied by fecal vomiting, and produces a marked local meteorism and intense tenesmus. In addition to these features the rectum cannot be made to retain more than one liter of fluid. The indications for treatment are as follows: (1) The volvulus must be relieved; (2) The intestinal tract must be immediately and subsequently evacuated; (3) The development of a peritonitis must be combated, and if it develops must be energetically treated; (4) A return of the volvulus must be prevented; (5) The collapse following the operation must be appropriately met. All of these indications are important, but especial weight is to be laid upon a thorough and immediate cleansing of the intestine.—*Finska Läkaresällskapets Handlingar.*

Addison's Disease Cured by Suprarenal Extract.—W. E. Deeks describes the case of a woman of thirty-two years, suffering from Addison's disease, with weakness, breathlessness, dizziness, headache, palpitation, lassitude, and loss of energy. Pigmentation was universal, but deeper, where pigment normally is present, on the exposed parts, where clothing bears most heavily, as neck, hips, and shoulders; also on the mucous membranes of the lips and cheeks. There was no response to various forms of treatment instituted, and it was decided to try suprarenal extract, three grains, three times daily after meals. Improvement began immediately, and within three days vomiting and diarrhœa began to lessen, and the patient began to gain strength and feel better. In two weeks she was very comfortable and enjoying her meals. Examination of the blood showed that hæmoglobin had increased from 32 to 40 per cent. In three weeks pigmentation was fast disappearing. Later reports showed that she was doing well.—*The Montreal Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 6, 1902:

SMALLPOX—UNITED STATES.

HYSTERIA AND ORGANIC DISEASE.

A STUDY OF THE DIAGNOSIS WITH REPORTS OF CASES.*

By CHARLES L. DANA, A.M., M.D.,
NEW YORK.
PROFESSOR OF MEDICAL DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE.

THE combination of hysteria with organic disease is a condition with which all physicians are familiar. It is one, however, which still presents puzzling problems, and one in which personal, prognostic, and medicolegal questions of grave character often arise. This is my excuse for putting on record some cases which illustrate these phenomena, and discussing the diagnostic questions which they suggest.

Grouping of Hysterical Symptoms.—The main objective stigmata and subjective symptoms of hysteria major may be grouped under five heads: (1) The anæthesias; (2) The contractures; (3) The palsies and tremor; (4) The attacks, and (5) The peculiar mental state. I leave out the various visceral, vasomotor, and glandular disorders which are either very rare or can be put in relation with the attacks and mental state.

Organic Diseases Commonly Found with Hysteria.—The hysterical syndrome is oftenest associated with organic lesions due to trauma, but the various symptom groups appear also with tumor of the brain, encephalitis, meningitis, multiple sclerosis, tabes, and more rarely with inflammatory disease of the nerves, as in one of my cases.

The Relative Stability of the Different Symptom Groups.—While the impress of the different groups of symptoms varies, there is a certain general law about them. The anæsthesias are the most mobile, fugacious, and amenable to remedial measures. They imply the most superficial involvement of the mind; they appear often to be only a disorder of attention or memory and they may occur without much or any paralysis.

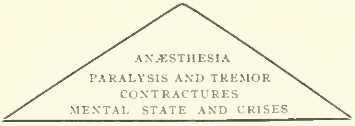
The paralyses indicate a deeper and more stable affection. They are practically always associated with anæsthesia, often with tremor, both of which are less stable symptoms, and the greater the paralysis the more profound this anæsthesia, while the tremor like the anæsthesia may exist alone. They show a much greater tendency to become fixed and in some cases of hysterical hemiplegia there is never entire recovery of the motor power.

Contractures may be fugacious and irregular-like anæsthesias, in the so-called contracture-diathesis, but when established in the severer types they are even more obstinate and difficult to manage than the paralyses. They do not disappear during sleep or even under moderate narcosis, and they act as though they were under the control of some subconscious center lying more deeply and more automatically organized than that which rules ordinary acts. Though originally the result of an emotion or an idea, the contracture gets beyond the power of any modifying mental process that can be directed to its control, and, as we know, in some cases an organic basis may be eventually developed for it.

The mental state of the hysterical with its associated crises, is the most profoundly established of all the syndromes, and necessarily so because in most cases it is inherent in the mind of the patient, and has simply been developed by an exciting cause. Hysteria almost invariably develops in a neuropathic constitution.

Thus on the elemental basis of the hysterical mind there develop, with progressively lessened stability for each, the groups of contracture, paralysis, tremor, and anæsthesia. This arrangement of the symptom groups, which is here indicated diagramatically, is not an absolute one. There are individual exceptions, but it will answer as a general guide.

Let me now say a word regarding these groups of symptoms in detail, and I trust to be pardoned if I go over some ground which is familiar.



The anæsthesias.—There are two types of the anæsthesias, the unilateral and the segmental, though they are often combined. Irregular areas of anæsthesia, was as hysterogenic zones, are largely incidental or accidental matters of suggestion. The unilateral type, or hemianæsthesia, is more extended and complete and uniform than that of organic disease which practically cannot simulate it. It is always accompanied at first with some anæsthesias of the special senses. These disappear, as a rule, sooner than the hemianæsthesia. The vision is affected oftener and longer than the hearing, smell or taste. The trigeminus is especially sensitive to the hysterical insult, while it is least affected in organic central lesions—still, even this nerve usually becomes normal sooner than the optic. The hemianæsthesia is more marked the more widely it is distributed over one side, and the greater the associated paralysis. Like hemiplegia, it may be deepest on the arm, and leave the leg and face before leaving the upper extremity, but usually hysterical hemianæsthesia is evenly distributed over one side. The profoundest types are nearly always associated with some paralysis and tremor, and when the muscular sensibility is involved the paralysis is still more surely present.

Hemianæsthesia may often be transferred or removed in part by hypnotic suggestion or cutaneous irritation.

The anæsthesias of the body, when not of the unilateral type, are distributed segmentally, *i. e.* by limb segments, not in root zones or nerve areas Trunk anæsthesias alone I have never observed. They are unstable and tend to disappear toward

---

*Read at a meeting of the American Neurological Association, June, 1902.

the periphery, passing from segment to segment, leaving first the hip, then the leg, then foot. There is never true and sharp dissociation of sensibility, though the pain and thermic senses may be more affected than the tactile, and these more than the deep or muscular sensibility. The tactile anæsthesia, as Mills observed, is more often only a hypæsthesia. Hysterical analgesia is not a true one in the organic sense, for hystericals practically never burn themselves. It has no accompanying pain or paræsthesia, though the patient may have independently headaches and neuralgias.

There is usually some paralysis with it, and the greater the paralysis the more profound the anæsthesia, just as with hemianæsthesia. It is only in decided paralysis that we get the muscular and deep sensibility involved. The temperature sense is more often disordered than actually lost. The limitation of the anæsthesia is not as sharp as in organic disease.

It is only in hysteria that we have anæsthesia of the whole of the body.

The tactile sense is usually a little affected in most cases, but it often remains relatively good long after pain-sense has disappeared.

Loss of deep sensibility and astereognosis is relatively rare. Even in profound types of hemianæsthesia with hemiplegia the position of the limb may be appreciated by the patient.

In general, it may be said that the hysterical monoplegias and hemiplegias carry with them the profounder sensory disturbances. In hysterical paraplegia, however, often no anæsthetic disorder is discoverable. Such cases are, in fact, rather functional spinal disorders than cortical or "ideal" paralyses like the hemi- and monoplegias.

The characteristics of the special sense anæsthesias I shall not refer to, as I have nothing new to offer.

The paralyses of hysteria are also of types that are usually easily recognized, and upon this point I hesitate to dwell very long. We know that those muscles which are symmetrically used, like those of the eyes, face, and respiration, as well as the involuntary muscles—in fine, the automatically used muscles—are rarely affected by hysterical paralyses. That there may be an hysterical ptosis and hysterical facial paralysis is true, but it is certainly extraordinarily uncommon, the monoplegias being the most frequent type and the hemiplegias next.

The general character of the hemiplegia with its absence of involvement of the face and its flaccidity and lessened reflexes is well known. The retention of the superficial reflexes which are absent or modified in organic hemiplegias is a point well insisted upon by Fraenkel.

Hysterical paraplegia is not infrequently diagnosticated, but to my mind, as I have already stated, these cases seem often of doubtful mental origin. They are usually functional disorders due to some spinal condition, for I exclude from this group the cases of astasia and abasia, which represent ideal paralyses of the lower extremities, and also those conditions known as amyosthenic, which come on in "attacks" and belong to the hysterical crises. The true hysterical paralyses are, as a rule, the mono- and hemiplegias. I do not, however, deny the occasional existence of hysterical paraplegia, but believe it must always be accompanied in some stage by anæsthesia.

It is extremely rare in hysteria also to have a quadruplegia—a paralysis, that is, not so much of the whole limb as of the hands and feet. One of my patients suffered from this type of hysterical paralysis and the rarity of this phenomenon makes it, I think, of some clinical interest. It would be impossible to make a diagnosis of an hysterical quadruplegia without there being a great many sypmtoms which would corroborate the diagnosis. But these existed abundantly in my patient.

Contractures.—The presence of contractures, especially in connection with apparent paralysis, furnish often most puzzling phenomena in hysteria. I have reported a case which was under long observation at the Montefiore Home, of a woman with hysterical contracture of the hand, which lasted for over a year and which simulated very closely a true organic contracture. It did not disappear in sleep nor under anæsthesia; it was, however, finally cured. The character of the contracture was determined more by the absence of other evidences of organic disease, such as atrophies and joint disturbances, and by the presence of associated subjective hysterical phenomena, and by the final cure. Some cases of hysterical paraplegias with contractures are extremely difficult to distinguish from organic disease, particularly if they are of very long standing, since we know that in very old cases actual spinal lesions may develop. There is sometimes no absolute criterion of the nature of a contracture except the associated phenomena. As a rule, however, it occurs suddenly and represents a condition of exaggerated voluntary contraction, while organic contractures are rather slow in development and are the sequelæ of paralysis. Hysterical contractures suggest the presence of an unconscious but extremely active volitional effort, and the patient seems actively to resist attempts at bending the part. They are not relaxed as the patient wakes from sleep or when in a warm bath. They may affect extensors as well as flexors, or both sets of muscles may act evenly, holding the hand or foot in straight extension. There is no trepidation or tremor or exaggeration of reflexes with the phenomena. There is a tendency for the smaller joints to become thickened by a periarthritis, so that some organic change is superadded in turn to the functional condition. Contractures usually affect a single member, such as a leg, foot, or arm. But that all four extremities may be involved is shown by my second case. Hysterical contractures usually affect segments of limbs, but sometimes involve the face, tongue, and eyes. It is the segmental contractures, however, which are the fixed and obstinate types. I do not know of any case of trunk contracture alone.

In hysterical contracture there is, then, an acute onset with no pain, no mobility, no cramp, no palsy, no atrophy or D. R., no exaggeration of reflexes or myotatic irritability, no morning relaxation, often no relaxation in sleep; there is an active resistance to attempts to remove it.

Hysterical contractures are, in my experience, much rather phenomena in this country than they seem to be in France. Amongst thirty cases of hysteria major with anæsthesias and paralyses I found contractures in only five cases. Sometimes the contractures occur without the characteristic anæsthesia, but are associated with pain.

It is by no means so easy to explain the grave contractures of hysteria, such as are shown in my second case, on the same theory as that by which we explain the simple paralyses and anæsthesias. It is easy to understand how a person can be anæsthetic in one limb through the influence of an idea, or how there can be a paralysis of it from a simple mental influence, but hysterical contracture often seems to be an active phenomenon, as if there were some separate personality at work upon the muscles, continually throwing vigorous impulses into the parts. According to Janet, the essential characteristic of hysteria is a doubling of the personality. Most of the acts of life are performed under the control of the ordinary or primary consciousness. But there is a secondary or subconscious collection of memories which is at work upon the organism also, modifying its functions or producing active changes in them. This secondary personality, which usually works automatically under the direction or at the stimulus of ordinary conscious volition, becomes dominant in hysteria, and it is this which, according to Janet, would produce the contractures.

The mental characteristics of the hysterical, aside from those shown by their anæsthesias and motor disturbances, are classified by Janet, into the stigmata and the accidents. The stigmata are: Amnesias, abulias, and modifications of character. The accidents are: Subconscious acts, fixed ideas, emotional and motor attacks and explosions, somnambulisms and deliriums. Under these heads Janet writes an interesting treatise. But he finds, I think, much more in the hysterical than strictly belongs to them. It is true that hystericals may be weak of will, may have no power of attention, may be peculiarly forgetful, may have morbid fears and doubting manias, may have attacks of automatism and somnambulism, mental confusion, deliriums and ecstasies, etc. But the majority of such disorders are more characteristic of the primary neurasthenics or of the abortive types of degenerative types of insanity, such as doubting mania, the various phobias, and the fixed ideas, than they are of the major hysterical, as seen here.

Morbid fear, doubting mania, and somnambulistic attacks may be imposed upon or associated with hysteria, but they are not characteristic of the types seen in ordinary practice, as I at least have seen the cases. The most characteristic trait is a kind of dementia or mental enfeeblement with a mental depression, amounting almost to melancholy, a lack of will to settle things, or to act, a weakness of self-control and an impressionability or suggestibility which is abnormal. There is a distinct change in character, this being shown in a greater lack of independence, a tendency to self-consciousness and diffidence, and a loss of former interests in life and their affections. There is a narrowing of mental activity and interest in every direction. These characters include some of Janets, but not by any means all, or the most striking of them. The development of morbid fears, of fixed ideas, of delirium, or any extraordinary amount of amnesia is not in the clinical picture.

It is understood that we are referring here to the state of the major hysterical and not simply to the so-called ordinary or "garden" product known as the hysterical woman who is usually only a very emotional, very selfish, and very foolish creature.

The attacks, or crises of hysteria, are, of course, characteristic enough phenomena, but in my experience they are relatively uncommon in major hysteria. There were no crises of any kind in the three cases which I report. It cn only be said that the original onset of the disease partook of the nature of a crisis.

In the diagnosis of hysteria the anæsthesias furnish the most certain criterion, and the paralyses are usually admitted as good helps. The fixed contractures are more puzzling, the tremor is very similar to that of multiple sclerosis or alcoholism, but can usually be readily detected by the associated symptoms. The mental state is most readily recognized when it shows a sharp differentiation from that previous to the onset of the disease. Crises may occur without indicating a fixed or major type of the malady; that is, they are incidental in many persons of unstable nervous system.

As to prognosis, anæsthetic hysteria without much or any paralysis is usually amenable to cure.

Profound paralysis, with great accompanying anæsthesia, is much more serious, especially if it lasts more than a few weeks. Most paraplegias get well or nearly well if there are not other grave, complicating stigmata, and this is still more true of monoplegia and quadruplegia. I think nearly all contractures are eventually curable. The mental state is the hardest of all to readjust. The older the case of hysteria, the more fixed it gets and the more difficult to cure. Still, we always regard hysteria as ultimately and essentially a curable malady.

Reports of Cases.—The following cases seem worth placing on record because one was accompanied by an autopsy which enabled us to prove that some of the anæsthesia was organic, but not all. Another case illustrates a universal type of agitation simulating alcoholic paralysis. The other cases have also some special interest, one of which, I believe, illustrates hysterical anæsthesia superimposed on the trunk anæsthesia of locomotor ataxia.

I am under great obligations to Dr. J. R. Hunt for his careful observations on three of these cases and for his preparation and study of the treatment in the second case. Also to my house physician, Dr. Hand, for his help in making observations and completing the records.

Case I.—**Fracture of Spine and Tranmatic Hysteria**—Mrs. R., aged twenty-eight years; married; admitted to Insane pavilion February — 1902, with a history of having jumped from a window while in a state of acute alcoholic excitement. On admission she was delirious and had to be restrained in bed, but there was, apparently, araplegia paralysis. The history obtained from her husband was that her father committed suicide and that two sisters were peculiar and hypochondriacal; that she had been on a drinking bout after her father's death several years previously, but was not habitually addicted to alcohol. Previous to her recent trouble and accident she thought she was pregnant and had been advised by a friend to take a quantity of alcohol to bring on a miscarriage. She followed this advice and got into a state of delirium, during which she jumped from a window thirty feet from the ground, landing on her buttocks on the stone pavement below. She had been drinking for several weeks previous to this. She had had a child born several years ago with great difficulty, and for this reason dreaded another pregnancy. She had been of a somewhat hysterical temperament, having occasional laughing and crying spells, but otherwise there is nothing abnormal about her history.

Her delirium was so marked during the first twenty-four hours in the pavilion that careful examination could not be made. At the end of that time she became quieter, and it was discovered that complete paraplegia had developed. She was seen by me at this time and ordered transferred to the general wards of the hospital. This was February 11. The record of her physical condition on admission, from Dr. Hand, house physician, shows that her general nutrition was good, expression apathetic. Eyes reacted to light and accommodation. Tongue coated and moist. Heart sounds weak; no murmers. Pulse rate, 128; respirations, 28; temperature, 100°. The lungs were normal, liver and spleen not enlarged. The extremities were anæsthetic and paralyzed. Knee-jerks present, also ankle clonus. Incontenence of urine and fæces. Arms were normal. Urine 1,024, dark, trace of albumin, no sugar. Microscopically, some blood and pus cells present. Three days later the urine was 1,022, alkaline, with slight amount of albumin, mucus, blood, and pus cells.

The patient was examined by me February 11, 1902, in the presence of the section class. She was then shown to have paraplegia, which was complete with absence of knee jerks and ankle clonus. Complete flacid paraplegia with anæsthesia extending from the feet upward to the third dorsal level on the left side on twelfth dorsal on the right.

The right side of the face in the distribution of the trigeminus was anæsthetic and the left side was normal. The right side of the tongue was anæsthetic, there was apparent total amblyopia of the right eye. Hearing on the right side was defective to bone conduction. Smell and taste were abolished on this side. There was some anæsthesia of the hands, not very distinct, and apparenty of the gauntlet type. The anæsthesia of the body extended from the third dorsal behind on the left side to about as far as the twelfth on the right side.

On February 12, the following day, another examination was made by Dr. J. L. Hunt. Palpation then showed slight prominence about the first and second lumbar vertebræ. There was also great tenderness to the right of the spine, and the whole lumbar and sacral regions were sore and the seat of pain. Corresponding to the spinal prominence points of hyperæsthesia were noted on either side, going about in a girdle shape. The mental condition is dull and apathetic, but the patient is not delirious. There are no cranial nerve palsies. The right arm is weak, but movements of both arms are present. Reflexes are present, no disturbance of sensibility or ataxia. Costo-hypochondriac breathing not impaired. Abdominal walls can be contracted, but owing to amount of fat, amount difficult to judge. Abdominal reflexes present on both sides. There is complete flaccid paraplegia. No knee nor Achilles jerks. No form of plantar reflex of any kind. There is absolute incontinence of urine and fæces. Anæsthesia and analgesia of buttocks and genitals, down back of thighs and legs, and both feet below malleoli.

There is now no anæsthesia above the limit of about the second lumbar distribution. Anæsthesia of face gone.

February 17.—Electrical reactions were taken of the muscles of the thighs, and they were found to respond to the faradic currents, direct and indirect. Femoral groups contracted sluggishly. The patient complained of constant, very sharp, shooting pains on the front of the thighs, also painful girdle sensation below umbilicus.

Movements of the toes and ankles are not appreciated, she feels the movements in the knees and hips, but cannot locate accurately. Movements cause pain in the back and sacral region. Ecchymoses and extravasations are present over the sacrum, but no bedsore.

February 13.—The patient's apathetic condition is still present. Pulse very rapid, running to 140. In the afternoon the patient passed into a semicomatose condition, in which she continued till the next day, when she became more conscious. On this day there was no incontinence of urine or fæces, but the bladder had to be catheterized. The patient took nourishment well.

On the fifteenth, right arm still weak, sensation good. Sensation of face and special senses normal. Incontinence of urine and fæces. From this time the patient's condition grew gradually worse. She became more comatose, temperature ran from 99° to 100°, till the 20th, when it dropped to 96.25. On the 23d, it rose to 97.75°, when she died. The pulse during this time ranged from 120 to 110. Respirations, normal.

Autopsy was made forty-eight hours after death. The spinal column was removed in toto, including sacrum and coccyx. Examination of the column and cord was made by Dr. Hunt. It was found at the first lumbar the anterior longitudinal ligament was ruptured. The body of the vertebra was fractured straight across about its middle with some comminution. The fragment projected anteriorly attached to the anterior spinal ligament. There was also a fracture at the junction of the left articular process with the lamella, so that the first lumbar spine was slightly movable laterally. The spine beyond the fracture preserved its natural features. All the ligaments between the twelfth dorsal and first lumbar were torn, so that the spine presented an abnormal mobility at the seat of fracture. Some of this may have been artificially produced at the autopsy. There was also fracture through the lowermost segment of the sacrum with extravasation of blood. The cord was removed by sawing through the articular processes posteriorly. No hemorrhage in the vertebral canal was found, except at the end of the cauda equina. Intermeningeal is a hemorrhage the size of a bean. The dura at the site of fracture had not been torn, although spicules of bone were projecting around it. Macroscopically, the cord was crushed in the upper sacral and lower lumbar regions. Conus medullaris maintained normal contour. On section no signs of medullary hemorrhage.

Sections of the cord were hardened and stained by the Weigert also hæmatoxylon, Niessel, and Marchi methods. The sections were made by Dr. J. R. Hunt and Miss Onuf.

These showed that the injury to the cord reached about as high as the second lumbar segment. Sections at this level show some slight crushing and distortion, but a fairly intact cord. Below this level the injury was more severe, affecting, however, almost entirely the parts posterior to the central canal, involving both posterior horns and the posrior columns, but leaving the anterior horns and anterior and lateral columns fairly normal. At no point was the cord crushed entirely across or destroyed throughout its whole extent, hence the flaccidity of the paralysis and loss of knee-jerks must have been due partly, perhaps, to the shock and partly to the injury to the posterior roots and horns at the upper lumbar level. Sections could be made directly from the part of the cord most injured. The lesion extended as low down as the sacral cord, and throughout its extent involved only its posterior portion. Secondary degenerations could be observed by the Marchi method in the lateral and posterior columns, following the ordinary course. In the neighborhood of the lesion there were the usual degenerative changes in the nerve; there were no hemorrhages and no evidence of reactive inflammatory process.

Case II.—Mary S., aged thirty years; occupation, sewing and housework; married ten years; four children, three miscarriages, three children living.

Family history.—No alcoholism nor neuropathic tendencies elicitable.

Previous history.—First commenced drinking two years ago, and for the first year drank only occasionally. Second year not so moderate, about every two or three months had drinking attacks, each lasting about a week. Drank whiskey, consuming half a pint a day. No drugs used. Is an excessive tea drinker, sometimes using as much as two quarts daily. Has had domestic troubles for past two or three years. Left her husband several times, and one year ago they separated. He left her. The three children were consigned to an institution in Worth street. After this she used alcohol more freely. About four months ago she first noticed weakness and staggering in the legs with numbness and tingling in the feet; at this time there was no weakness nor paræsthesia in the hands. This lasted three weeks. During this time she began to notice weakness in the hands; if she went to pick up an object it would fall out of her hands. Slight numbness in hands.

The day of the onset of the rigidity she had had very severe, sharp pains in the legs with muscular contractions, accompanied by what the patient described as "a tightness and drawing sensation" in the epigastrium, simulating a true girdle very closely. The rigidity came on rather suddenly at 10 P.M., March 16, 1902, Sunday, while the patient was on the street. An ambulance was summoned by a policeman. She was admitted to the alcoholic pavilion of Bellevue.

Examination—(J. R. Hunt).—At examination one week later the following status was made:

There was marked gross tremor of the arms, head, lips, and tongue which was increased on intention. The tremor was so violent that the patient was held by a nurse. Odor of alcohol on breath. The patient was extremely excited and had been somewhat wandering during the preceding night. The entire body was rigid, especially below the waist line, so that the limbs and trunk could be lifted and supported by the heels. The arms were flexed, also the fingers, the legs were extended and the feet in pronounced plantar flexion, as were also the toes. The spasm in the arms could be overcome, but not without causing pain. Those in the lower extremities resisted all efforts, the manipulation causing considerable pain. There was voluntary movement in the arms, but none in the lower extremities. The heart acted very rapidly, the sounds were loud but clear. no murmurs. Respiration rapid and equal. The pupils were dilated, all reactions present, ocular excursions normal. Facial innervation normal. also palatal and lingual, but accompanied by gross tremor, as noted above. The tendon reflexes in the arms were exaggerated. In the lower extremities, owing to the rigidity, not elicitable. No plantar reflex elicitable in lower extremity. No abdominal reflexes elicitable. The examination of the spinal column was negative, but movements and manipulation caused great pain, referred to the lumbar region. For one week after admission the patient was catheterized every six hours. There has been no recurrence of this, the bowels are constipated. There was no vomiting at this time and no evidence of wrist-drop.

Sensory examination at this time (see chart) showed complete absence of tactile, pain and temperature sense from the level of the navel to the toes. This included also deep sensibility, although deep muscular pressure could be distinctly perceived. The direct manipulation of the nerve trunks and muscles at this time caused no pain. There was general analgesia or hypalgesia of the face, head, arms. and trunk, with the exception of a band around the navel corresponding to the aforesaid girdle feeling. The tactile sense in this area was not distinctly disturbed.

The special senses on the left side—sight, hearing, taste and smell—were lost. Present on right. Conjunctival and corneal reflexes were absent or only suggested on both sides.

Was admitted to the medical ward 22, Bellevue, April 1, 1902. At this time bilateral wrist-drop was first noted. The tremor of the face, tongue, and arms had practically disappeared, and only returns in the arms under some unusual excitement. The contractures in lower extremities are as noted. The trunk is fairly mobile.

Sensory examination showed anæsthesia of the hands from the wrist down (glove anæsthesia) and in the lower extremity from the knee down (stocking anæsthesia), including all forms of sensation, deep as well, only deep sensibility is limited and not entirely lost in these regions.

Electric examination at this time showed normal reactions in the arms to the galvanic and faradic currents.

April 22.—*Status*. Cranial nerves negative. Upper extremities. Hands are in position of bilateral wrist-drop, more complete on left. If the hand is lifted it drops heavily. On elevation of hands contractures of flexors of wrist are noted. but can be overcome especially palmaris longus. Muscles of shoulder girdle and upper arm not paretic. In the flexors of the hand and fingers both of which are in a state of contracture, when voluntary effort is made no force is exerted. No movement is induced. The same is true of the intrinsic muscles of the hand corresponding to the ulnar nerve. Contractures in lower extremities practically as noted Slight motion is possible in ankle and hip-joints. Also in joints of toes. All these cause pain. The calves are tender on very slight deep pressure. This is not true of the soles of the feet.

Note. Urine 1,025, acid, no albumin nor sugar. Dense white sediment, negative. Temperature in medical ward averaged 99°. Respirations at times very high, at times as high as 64. Pulse inclined to rapidity, rarely under 80, sometimes 118.

Ears poorly formed, especially helices; Darwinian tubercle on left. Torus palatinus. Abdominal reflexes present, but weak. Hearing little diminished on left, and there is contraction of both visual fields, especially left, to form. No hysterogenic zones. Tenderness over fundus uteri. Any effort to overcome contractures causes pain, but pressure over nerve trunks is negative. Myotonic irritability increased in arms, diminished in lower extremities. No myoid tumors. There is occasional tremor of left foot and of both hands, especially under excitement. During last menstruation had attacks of vomiting, and during electrical examination developed hysterical crisis, which lasted for several hours, accompanied by vomiting, paroxysmal tachycardia, increased respiration, and intense mental excitement.

Sensation (see Chart).—Over entire left side sensation to pain is diminished or lost. The degree varies from time to time. On right side pain is felt, but not acutely. Over the upper extremity from the elbow to finger tips light touch and temperature sense are lost. From wrist to finger tips loss of pain sense. Sensation of pressure and articular sense well preserved, except in finger tips, where there is uncertainty. Localization of deep pressure is good. On lower extremities there is loss of pain, touch, and temperature senses from knee to tip of toes. Deep pressure is felt, but causes no pain. Contraction of both visual fields to form, especially left.

Electrical examination. May 1, 1902.—Muscles of arms and legs react to faradic current when applied directly and indirectly. Likewise to galvanic, directly and indirectly requiring in the lower extremities fairly strong currents, 10 to 15 m. a. There is no change in   in either extremity. The muscles of the calf (   ) do not produce any locomotor effect (contractions).

CASE III. **Traumatic Hysteria; Contusions; Injury and Burn of Hand; Contraction; Anæsthetic**

Stigmata of Hysteria.—Mr. Henry C. K—— aged fifty years; married; one child; business manager. Temperate all his life in alcohol and tobacco, had no serious sickness, only slight bilious attacks. No nervous disorders, no syphilis. Perfectly well at the time of his accident. Was in the last car on the train which was crushed in the collision in the Grand Central tunnel, January 8, 1902, in the front of the car. All that he knew was a crash, until he found himself in the midst of a mass of wrecked timbers and human beings. He was helped out and taken to a hospital, where it was found that the tenth rib on the life side was broken and the right knee contused. Righ hand burned, he says, in the third degree, right shoulder, arm and side of head burned. Taken to Flower hospital, where he had severe vomiting; not unconscious. Kept there two weeks and four days, then went home, where he remained. Was in bed for about two weeks. Two weeks after the accident and before leaving the hospital began to have tremor in both hands, could not sleep well, was very nervous while at the hospital, and had to be given anodynes. Since has been nervous and depressed; had sweats and palpitation, sleeps poorly, only about two hours a night. Memory poor, cannot read nor fix attention. Has dizzy turns, but no loss of consciousness. Is unable to walk well on account of injury to legs, and when he does walk holds his back very stiff. Right arm and hand, which were burned in accident, show tremor of large oscillation.

Examination showed systolic murmer over heart. No lesion of lungs nor viscera. Urine normal. Walks with limp. No decided paralysis. Right hand in state of extension, rigid, cannot be shut. Right arm in constant tremor, so he cannot use it. No paralysis of cranial nerves nor of lower limbs. Knee-jerks feeble on right, normal on left. Dynamometer, right 0, left 20. Tongue protrudes evenly. Left side of face rather more innervated than right. Pharyngeal reflex present. Anæsthesia to touch and pain over right side of face, tongue, and distribution of trigeminus. There is a concentric limitation of the visual field on the right. Loss of bone conduction and some aerial conduction on right side, smell on right side, and taste on both sides. No babinski. Hand in state of resistant extension. No apparent arthritis or evidence of articular inflammation, no scars, the rigidity seems to be of an hysterical kind. Attempts to close the hand are resisted. There is no pain.

Case IV.—**Tabes and Hysteria.**—Male, aged forty-five years; denies lues; no alcoholism; has been a very hard worker. About one year ago noticed neuralgic pains in the distribution of the left trigeminus. About three months later these disappeared, and he began to have girdle pains and about the level of the third and fourth dorsal, accompanied with a great deal of nausea. These persisted and were so severe that the patient came under my observation. He then showed some static ataxia, Argyle-Robertson pupil, slight hand of hypæsthesia in the course of the third and fourth dorsal segments on each side, but more upon the left. He had also weakness of the bladder and occasional nocturnal enuresis. He was very nervous, mentally depressed at times, having occasional attacks of hysterical crying. He had suffered a good deal from domestic strain and personal misfortunes. In the six months that he was under my observation he developed hyperæsthesia of the chest and analgesia of the extremities down to the ankles, the feet being normal. There was some slight hyperæsthesia and dysæsthesia also over the region in which there was analgesia. At one time he was observed to have this analgesia reaching to the wrists of both extremities, but not involving the hands. The hyperæsthesia here being accompanied with a very slight amount of dysæsthesia. Thermic sense was, if anything, exaggerated. The muscular sense or deep sensibility was not disturbed.

THE FAMILY PHYSICIAN OF THE PAST, PRESENT, AND FUTURE.*

By S. A. Knopf, M.D.,
New York.

Mr. President and Fellows of the American Academy of Medicine:

The family physician of the past still lives in the memory of many of us. He was not so rare an individual in years gone by as he is now. In most families the family physician was an indispensible, important, and sometimes a very dignified personage. He was a hard-working man, seldom of wealth, but universally beloved, and revered by all. He was rarely feared, except now and then by the smaller members of the family, who thought to have reason to dislike him at times for his seemingly autocratic behavior. Yet, as a whole, he was the friend of all, the advisor of the family in many matters even not purely medical. He was the confessor of many a troubled heart, old and young; his remuneration was not large; he was often paid by the year a round sum, which, when there was much sickness in the family, made the average pay for a call ridiculously small. Yet he did his duty unswervingly. He would drop in to see the family whenever he was nearby or could spare the time, although he knew that all were well. In many families he had seen the children grow up from babyhood, for it was he who helped the mother when the little strangers arrived.

Could all the pleasant, touching, and heroic incidents be told in connection with the old family doctor as many of us knew him, it would be a revelation to many a young physician who now starts out in life with the sole aspiration to establish himself in a great city and become a great consulting physician, or a great surgeon, known for his operative skill, the great number of capital operations he had performed, and the great throng of students who flock hither to hear him or to see him operate. The old family practitioner, who in many instances was, indeed, the physician of the soul as well as of the body to those intrusted to his care, to whose true, heroic, and humane picture my pen, I know, cannot do justice, is gradually passing out of existence.

I do not mean to say that there are no more family practitioners, but I believe you will all agree with me when I say that there are few of the old type of family physician left. The present family physician is not held in nearly as high esteem as our fathers and fathers' fathers in medicine were held. Furthermore, I believe, you will also bear me out when I say that there are now fewer family physicians absolutely and relatively to number of population than there were fifty years ago.

Who shall be held responsible for this decrease in numbers of family practitioners, the decrease in esteem, this depreciation of a once so exalted position? No person, no one class, but rather scientific events and our present social conditions are the cause of this disappearance, and the disinclination of many even well-to-do families to attach to themselves a general practitioner as a family physician. The discoveries in bacteriology and in sanitary science. the wonderful strides made in surgery, the multiplication of specialties, and last but not least, the multiplicity of different systems of medicine, such as homœopathy, eclecticism, etc., not to mention Christian scientists, faithcurists, ostheopaths, somopaths, and other paths, are responsible for the passing away of the older type of family physicians.

---

*Address delivered before the American Academy of Medicine, at the annual meeting at Saratoga.

The family physician of the present is rarely held in just esteem. In some families he is called in simply to decide what specialist should be consulted; in others he is allowed to attend to minor ailments, while in serious cases the specialist is often called in without the family physician being consulted. Again, individual members of one family often manifest a preference for this or that system of medicine. Having myself had for a preceptor one of that old type of physicians who could not bear the idea that there should be any but the one regular school of medicine, and to whom the designation allopath was as distasteful as homœopath, I had imbibed his dislike, his distrust, and his disdain for any system of medicine but the regular. Shortly after graduation, I was fortunate enough to become the physician to a very nice and cultured family. I had been successful in attending the head of the family, and I flattered myself to have gained thereby the confidence of all the members. Soon, however, I found out that I never was called in when any of the children were sick. I endeavored to comfort myself with the belief that it was probably my youth which was the cause, and that these good people did not care to trust the precious lives of their children to so young a physician. A subsequent, event, however, taught me that it was not discrimination against me, but rather discrimination against the school of medicine in which I had been reared and to which I was so proud to belong. One day I met a homœopathic physician coming out of the house of this family, and later I received the explanation from the father to the effect that his wife would never allow her children to be treated by any physician except by one belonging to the homœopathic school. My idealistic conception of a family physician received a severe shock, and has received a good many more since. I now know of a family where the husband goes to a physician of the regular school, the wife to an osteopath, the two daughters to a homœopathic lady physician, and the mother-in-law to a Christian Scientist.

As I have said before, there are, of course, some general practitioners who have a number of families which they attend exclusively, but even their position is not an enviable one. To be frank, as things are now I do not blame the young medical man when he dislikes the idea of becoming, and always remaining, a general family practitioner. Physicians are entitled to financial prosperity as much as any other profession or trade. Ours is a liberal profession. It has its ideals and its ethics, and has also the reputation of being the most unselfish of all professions, and I pray that it may remain forever thus. Yet, we are men, husbands and fathers, and we too would like to see our loved ones in comfort. When we lay down our burdens, or when we are called off suddenly, when we fall victims to the fulfillment of our duties, we, too, would like to feel that our wives and children shall not be in want. Now, there is no gainsaying that, when we compare the earnings of the specialist with those of the family practitioner of the present day, the latter is at a great disadvantage. Supposing the general practitioner calls in a great surgeon to confirm his diagnosis in a case of appendicitis and an operation is decided upon; whether the patient is taken to a private hospital or operated at home, in the majority of cases he passes completely out of the hands of the general practitioner. The surgeon has his own assistants who aid him during the operation and attend to the dressing of the wounds of the patient until his complete recovery. The great surgeon receives from $500 to $1,500 for the operation and the family physician, who was the means of saving a life by a timely calling in of the surgeon's service, receives from $2 to $5 for his visits, according to the circumstances of the patient. It is this great discrepancy between the remuneration of the services of a great surgeon and those rendered by the conscientious, honest, and faithful family practitioner, which makes the young men decide on their specialty while yet in the third or fourth year of their college life.

Now I do wish to state right here that nothing is further removed from my mind than the wish to minimize the value of specialism. The field of modern medicine and surgery is so vast that not even the most brilliant mind, the most skilful operator, could master it all. As medicine and surgery stand to-day, it is simply beyond the capability of human intelligence to be a great diagnostician of internal diseases, a great surgeon, gynæcologist, obstetrician, oculist, laryngologist, and aurist at the same time. Men who devote their whole lives, their whole energy to the study of one of the many branches of medicine must ever be the counsellors and teachers of the general practitioners.

The relation between specialist and family physician could, however, be changed to the advantage of the latter without detriment to the former. Let me take again the illustration of the great surgeon who is called in to confirm the diagnosis of appendicitis made by the family practitioner and who receives, say, $500 for the operation which follows. Would it not be perfectly just if the after-treatment, such as dressing the patient's wounds and watching over him to see that no mishap occurs, would be left to the family physician, for which he would receive a remuneration a little more in proportion to the fee charged by the operator? Were such a practise in vogue I am convinced many a general practitioner would feel more kindly disposed toward some of our great operators than they do now, and the family physician of the present would rise to a higher level of importance and esteem than the public of to-day is willing to concede to him. There is much which the consultant, the great surgeon, or celebrated specialist in other branches can do to bring the standing of the family physician of the present day to a better recognition and appreciation on the part of the family by which he is engaged.

I have spoken of the family physician of the past and of the present, and now permit me to picture to you the family physician of the future, such as I see him in my mind's eye, such as I wish he might be while this twentieth century is still called new, and such as I know you all would wish him to remain as as long as mankind is heir to disease. The tuberculosis problem in which I have been interested for a number of years, has taught me many things which are applicable to general medicine, to the duties and vocation of the family physician, and to the solution of the social position of the general practitioner of to-day. The one positive conclusion I have arrived at, through what I believe an earnest, unbiased, and careful study of the subject, is that the tuberculosis problem will and can never be solved without the help of the family practitioner, and that consumption as a disease of the masses will never be succesfully combated until the day in which every family has its family physician No matter how strict the sanitary regulations which boards of health may issue, no matter how many sanatoria and special hospitals for the consumptive poor we may have, we must look to the family physician for the bulk of the work in fighting the "great white plague." We must look to the family physician for the discovery of the early and curable cases; we must look to him for the carrying out of the sanitary regulations; without him our sanitary ordinances will do only half the work they are intended to do. Without the family physician only the more advanced and often hopeless cases will come to our notice. Without the family physician for rich and poor, and particularly for the poor, there will be a constant supply of new tuberculous cases, created daily in the unsanitary tenements of the poor.

What has been said of tuberculosis is certainly applicable to nearly all other diseases. Most ailments increase in severity where nothing is done to check their progress. Many diseases have their etiology in ignorance, and here again you will have to pardon me if I use for illustration that most characteristic disease of the masses, namely tuberculosis. Malnutrition of the poor we are apt to attribute to want of food. Those of us, however, who have some experience in the tenement-house life of large cities will know that there is relatively more waste of food substances in the houses of the poor than in the houses of the well-to-do. It is often nothing but ignorance on the part of the willing but untrained housewife of the laborer which makes his food expensive, but not nutritious. The poor girl from the shop or factory, when she marries, does not know the art of choosing the right food and preparing it appetizingly and tastefully, The result is often not only malnutrition of husband, wife, and children, but, alas! also discontent, love for stimulating liquors, crime, and disease. In a wealthy family, if a child or grown person grows thin in spite of plenty of food, the family physcian would be consulted, and not infrequently would discover the cause of malnutrition to be the fact that the food given to the patient was not of the proper kind, and, with a change in the right direction, the patient would improve. The poor alone have no one to turn to for advice; they only go to the dispensary when really sick; they have neither time, nor are they observant enough to discover slight ailments, such as an impaired digestion and lack of assimilation, conditions which are the true forerunners of consumption and other grave diseases. Again, those familiar with the life of the ordinary workingman will know how he and his family often shrink from the thought of entering a hospital. These men will make all possible sacrifices in order to keep the sick member of the family at home and provide such medical attendance for him as they are able to procure. But timely and regular attendance is rather the exception than the rule among poor families where there is a consumptive or any other kind of invalid. These poor people will first try all kinds of quack remedies, ask their druggist for advice, or, attracted by some glaring advertisements of a sure cure for consumption or all other ailments, fall into the hands of some unscrupulous charlatan.

It is evident that there would not only be a direct benefit to the families of the laboring classes from timely and judicious treatment of any of their sick members, either at home, in a hospital, or in a sanatorium, but the community at large would be a direct and indirect gainer. By providing, for example, medical attendance to families unable to pay a regular physician, or by placing the consumptive patient in a sanatorium in time, the pulmonary invalid has 75 per cent. of chances to be cured, and is prevented from infecting his own kin and neighbors. Seventy-five out of a hundred consumptive patients will be prevented from becoming burdens to the community. All this would be direct gain to the community, but the indirect gain to the commonwealth by curing and making strong and useful citizens of seventy-five out of every hundred tuberculous persons, who were otherwise doomed to death in the prime of life, is well nigh beyond calculation.

There is no doubt that tuberculosis and many other diseases of the masses can and should disappear in civilized countries, and it devolves upon us medical men of the twentieth century to devise means and propose measures to our municipal authorities, State legislatures, and philanthropists that will best accomplish this much-desired end. The old Scotch proverb "an ounce of prevention is worth a pound of cure" is applicable in all diseases, and particularly to phthisis pulmonalis. We all acknowledge Koch's bacillus as the true etiological factor in tuberculosis, but we also know that in health the accidental inhalation of a few bacilli, the swallowing of some tuberculous milk, or even a scratch infected with tuberculous matter, are really of any consequence. The healthy nasal secretion is batericidal, the ciliated epithelium of the upper respiratory tract is a physical hindrance to the bacilli. The gastric secretions, too, are, in a large measure, bactericidal, and the phagocitic power of the white blood corpuscles is, in the healthy individual, the best safeguard against the invasion of the bacilli.

It is the badly-housed, underfed, overworked people, weakened by disease, intemperance and excesses, who soonest fall prey to the tuberculosis bacillus and to the germs of all other infectious diseases. The family physician employed by the municipality would insist that the dark, dreary, badly-ventilated tenement-house must disappear By giving to the laboring classes better tenements, where sunshine, light, and air are plentiful, with at least six hundred cubic feet of space alloted to every individual, we will save many a one not only from becoming tuberculous but also from becoming a prey to other diseases.

Phthisiogenetic diseases, such as smallpox, scarlatina, measles, or girp, are all diseases, which the earlier they are discovered the more chance there is of their taking a favorable course. The one who discovers the first among the well-to-do is the family physician. He may discover the early symptoms of these diseases on his regular visit before the sufferer himself has an idea of being a patient. In the family of the poor the disease must be far enough advanced for a layman to discover it before medical aid can be hoped for.

What great good cannot the true family physician accomplish by a regular periodic examination of the chests of a family entrusted to his care! Venereal diseases, excesses and intemperance may be classed under one heading, and may be called a trinity of evils resulting from ignorance. While the social reformer and clergyman may do their grand work in helping to combat them, again the family physician has to do the bulk of the labor. He who should be, and often is, the confidential friend of everyone of the family, old and young, will be best able to warn the young man of the danger which besets him when starting out in life. If a member of a family has been unfortunate enough to contract a venereal disease, the family physician will see that proper treatment is instituted and all precautions taken to prevent infecting others or a reinfection of the patient himself. Again it is the family physician, friend, and advisor who may exert the most beneficent influence on old and young by pointing out to them the danger of excesses of any kind, and particularly intemperance; for let us not forget that alcoholism is not only one of the most important phthisiogenetic diseases, but also the cause of a number of the most serious nervous and mental disorders, leading, alas! too often to crime and moral degeneration of whole families. In some European sanatoria for tuberculous and scrofulous children, statistics show that more than 25 per cent. of the little inmates are of alcoholic parentage. You know that our insane asylums harbor from 40 to 60 per cent. of patients in whom the anamnesis shows alcoholism to be the true etiological factor.

The physician acquainted with the tendencies of the individuals entrusted to his care will know when to sound the note of warning. He will be able to combat the idea which is still very prevalent among the laity that alcohol is a good remedy for consumption, a good remedy in stomach disorders, or an indispensible stimulant to the worker. The physician will exert all his influence to show that alcohol is not a food, but, when taken in excess, a dangerous, powerful poison, destroying body and soul, undermining the strongest constitution and causing untold misery and want in many once happy and prosperous families. With such a medical advisor given him by a wise and beneficent government, the honest but poor laborer will be protected from tuberculosis and other diseases, and the moral influence which the true physician can exert in these environments must be of incalculable value to any community.

Mr. President and Gentlemen, if from what I have said you have already partially divined my conception of the family physician of the future, permit me to complete, or rather summarize, this conception in the following words: The family physician of the future will be the cultured, refined gentleman, who through his college training has been duly prepared for the great profession he has chosen to follow. A five-years' course in a medical college, not owned or controlled by a private corporation, but by an endowed independent university or State institution, and an additional year of obligatory general hospital training will have fitted him to be a sanitarian, a skilful physician, a trained general surgeon, wise enough to know when council is needed; a physician to be engaged by a number of private families among the well-to-do or by the government as a guardian of health of a certain number of indigent families. In both cases his remuneration should be large enough, so that he can perform his duties without worry for his daily bread. Leisure and opportunities should be at his disposal, to follow occasionally some special scientific pursuits, if he is so inclined.

The family physician of the future has, to my mind, a mission to perform, so high, so noble, so unselfish, that only the best of men, the greatest souls would wish to aspire to fill such an exalted position. The work which this family physician of the future has to fulfill is greater than that of the family physician of the past or of the present. He will rise in importance and in recognition to the highest level in his social as well as in his professional relations. To him the statesman, the social economist, the philanthropist must look for help; for the family physician of the future, whether practising in the palace or in the hut, in the crowded tenement of the metropolis, or among the peasants in the far-off hamlet, will be the leader in the physical and moral improvement of the race, and in making the men and women of the twentieth century true images of their creator.

A GUNSHOT WOUND OF THE ABDOMEN, INFLICTING NINETEEN PERFORATIONS OF THE INTESTINES AND FOUR LACERATIONS OF THE MESENTERY, WITH RECOVERY.

By ROBERT F AMYX, M D.,
ST. LOUIS, MO.

The patient, John Walker, colored, aged twenty-one years; nativity, Mississippi; occupation, laborer; social condition, single, was received at the St. Louis City Hospital at 7.10 P.M., December 11, 1900. Present condition: The patient received a gunshot wound of the abdomen about one hour before coming to the hospital. Examination revealed a wound of the right iliac region, just above McBurney's point. The patient was immediately prepared for operation, the usual antiseptic and aseptic precautions being observed. After thoroughly washing and antisepticizing our hands—this procedure requiring about twenty-five minutes—the patient was placed on the operating table and anæsthetized, chloroform being used. At 8.15 P.M. an incision five inches in length was made at McBurney's point. On attempting to palpate the intestines, after entering the peritoneal cavity, I was surprised to find the intestines walled off by firm adhesions; the latter were between omentum, ascending colon, and cæcum. The adhesions were torn and an entrance made in order to reach the small intestines. It was then found that the omentum was attached to the entire right side of the peritoneal cavity, dividing this cavity into two closed spaces, the one above containing no intestines, while the under one contained the small intestines and the sigmoid flexure.

The small intestines were delivered through the rent in the adhesions and examined. The perforations found were as follows: Two just above the cæcum in the ascending colon, one about three inches from the cæcum in the ileum, two in the ileum about three feet from the cæcum, twelve were in the lower portion of the jejunum, these were distributed very closely within eleven inches of the intestines, the latter were very badly contused and lacerated; finally, two more perforations were found in the sigmoid flexure. The two perforations just above the cæcum and in the ascending colon were separated by a mere band of intestinal tissue; this was cut away and the edges of the wound enlarged, so that all of the contused and lacerated tissue was removed, and when the perforations were closed, normal tissue was approximated instead of devitalized contused tissue, as would have been the case if the edges of perforations had not been cut away.

The Czerny-Lembert suture was used in closing the perforations; seven separate perforations were closed in this manner, while that portion of the jejunum which contained the twelve perforations was resected, and an anastomosis of the intestine was made with Murphy's button. In addition to the perforations in the intestines, there were four rents in the mesentery; two of the rents were in that portion of the mesentery immediately below the gut in which the twelve perforations were situated. These were removed when making the resection of the gut; the other rents were sutured, as the blood supply to the gut beyond these points was not disturbed.

The procedure which caused greatest difficulty was in suturing the perforations in the sigmoid flexure; the adhesions were so firm at this point that it was very difficult to deliver the gut through the opening in the right iliac region.

The abdominal wound was enlarged downward until a better field for work was secured. The perforation in the anterior wall of the gut was comparatively small, while that in the posterior wall was about one and a half inches long, the bullet having passed through obliquely.

After inspecting the entire length of the gut for further wounds and satisfying ourselves that there were no more, the peritoneal cavity was flushed out with normal saline solution; twelve gauze drains were inserted in the various recesses of the peritoneal cavity, viz., above the omentum, below the omentum, above and below the mesentery, into the pelvis and up toward the liver, so that the drainage was established above and below the liver.

This procedure has been practised at the City Hospital for the past two years with gratifying results in gunshot wounds of the abdomen. After placing the drains the abominal wound was sutured and reduced to a small size, so that the drain could not be forced out by the straining efforts of the patient. An abdominal pack of chloride of mercury was applied and the patient placed in bed; the head of the bed being elevated about fifteen inches, so as to facilitate drainage in the direction of the abdominal wound toward the pelvis. The time occupied in performing the operation was three hours. The patient stood the long, tedious operation very well. The pulse was 120, respiration, 36; temperature 100° F. The course of treatment after the operation was as follows:

December 12: Slight tympanites present; no distinct signs of peritonitis. One-tenth grain doses of calomel were given every hour until one grain had been taken; this produced one small action from bowels. The patient vomited on several occasions. Three drops of carbolic acid were given twice during the day; the vomiting disturbed the patient considerably, and I decided to give him seidlitz powder; this was allowed to effervesce, so that most of the carbon dioxide was discharged before giving it to the patient; with this, three drops of carbolic acid were given; there was cessation of the vomiting after this.

The patient's condition remained unchanged up to December 17, when there was a decided change for the better. During this period six to eight drops of carbolic acid with a seidlitz powder were given daily; there was a free movement of the bowels daily, and the patient did not complain of any discomfort. The tympanites which existed immediately after the operation subsided.

His condition continued to improve. On the tenth day after the operation Murphy's button was passed. For several days previous to this date the patient had complained of pain in left gluteal region. Examination revealed a tumefaction with fluctuation at this point; the parts were antisepticized, cocainized, and an incision was made; about half a pint of pus escaped. On inserting my finger into pus cavity I felt a bullet imbedded in the tissues; it was extracted and found to be of 44-caliber. After this the temperature, which had been increasing, began to decline. On third day after the pus and bullet were removed his temperature was 100° F. His condition continued to improve steadily, and he was discharged from the hospital March 4, having completely recovered.

During his first fifteen days the patient was nourished by liquid diet only, no solid food of any kind was given until his temperature began to decline; a semi-fluid diet was then substituted, such as custard ice-cream, whey, and peptonized milks, so that the approach to solid diet was gradual.

I wish to call attention to the manner in which the drains were removed. Instead of removing the entire drain at one time, only a portion was removed each time, so that drainage could continue along each tract made by the individual drain until the tract closed behind the drainage material; this procedure was carried out with each drain.

Some criticism may be made of the site selected for the abdominal incision. The reason the incision was made at McBurney's point was that it was at a point where the bullet when passing through the peritoneal cavity would most likely injure the cæcum or the ascending colon. When this incision was made, it was decided that a median one would also be made if the conditions present should justify such a procedure; this was unnecessary, as it happened that all of the injured viscera could be examined through primary incision. The points I wish to emphasize are as follows:

(1) The edge of each perforation was cut away in order to get into normal tissue, *i. e.* tissue which was not contused; so that when the edges of the wound were brought together, repairing process would be more rapid and certain than it would have been if the contused edges of each perforation had been turned in. There can be no doubt that contused tissue around perforations made by bullets often break down; this process going to and often beyond sutures. This condition has been demonstrated in post-mortems. From this observation I believe all perforations produced by a bullet should have their contused edges cut away before closing them.

2. Whenever we are dealing with gunshot wounds of the abdomen with perforation of the intestines by a bullet, drainage should be instituted. It is impossible to estimate how much infectious substance is carried into the peritoneal cavity by the bullet from outside of the cavity. When the bullet passes through the intestine it carries with it the contents of the organ. Besides this, the contents of the intestine will also pass through the perforations into the peritoneal cavity, so that there is a certainty of a widespread infection; one that is not removed by the flushing of the peritoneal cavity in a degree thorough enough to satisfy one that the peritoneum can take care of itself afterward.

3. The infectious substance is not the only factor to deal with. The manipulation of the abdominal viscera always produces a slight degree of contusion, so that the momentary lowering of the vitality of the peritoneum in the presence of infectious media, in many instances, terminates in a peritonitis of a varying degree.

4. The drains should not be disturbed before the fifth or sixth day, and then only a small portion should be withdrawn at a time. This manner of withdrawing the drains allows a better drainage than by an immediate removal of the entire length of the drain.

5. The diet in the above case was a liquid one up to the fifteenth day; after this period a gradual increase to a solid one, covering a period of one week.

6. The number of perforations made by the bullet was remarkable. The number of perforations in

the gut which was removed, *i. e.* twelve in eleven inches of intestine.

I have the resected portion of the intestine, which was inspected by the members of the society before which this report was read. I was unable to present the patient, as he was convicted of manslaughter after recovering, and is now serving a two-years' sentence in the penitentiary. At some future time I may have the opportunity of presenting him to the society.

NASAL DISTURBANCES IN TYPHOID FEVER AND THEIR SEQUELÆ.

By DR. MAX TOEPLITZ,
NEW YORK.

Among the nasal disturbances in typhoid fever, epistaxis was until recently the only familiar phenomenon, and it was considered as a sign of the general affection. The rhinoscopic examination of the condition during the course and after cessation of the disease was seldom, its treatment never, resorted to. Nevertheless, it is worth while to examine the nose in every case of typhoid fever, and to treat the disturbance found, since, not so infrequently, quite disagreeable disturbances are experienced over an extended period.

The nose and the nasopharynx present, during typhoid fever, the state of a dry catarrh. The mucous membrane is usually reddened and loosened, and it frequently appears, particularly upon the turbinated bodies, in a deep, dark red, and velvety swelling. The secretions are sparse. The entrance and anterior portion of the nasal cavities often present a fuliginous deposit, whereby, together with the narrowing of the cavities, mouth breathing is produced.

The usual signs of coryza, such as sneezing, increased discharge, etc., are exceptional. The hyperæmia of the nasal mucous membrane is frequently so intense as to exude sanguinolent mucus by mere cleansing of the nose. Upon the anterior portion of the septum an erosion containing thrombosed vessels or blood eschars is the frequent cause of the bleeding. The nutritive disturbances caused by the bacillus Eberth, or, more probably, by its products, produce the bleedings in conjunction with the abundance of capillaries, the vulnerability of the anterior portion of the nasal septum, and the fragility of the vessels.

The bleedings occur in 50 per cent. of the cases during the stages of incubation and the first fever, more rarely in the beginning of the second week, while they decrease at the height of the disease, to become again more frequent during the last fewer days and during convalescence. Epistaxis may frequently return during a brief period, and may occasionally become so intensified as to form a great danger; and, in fact, some patients have bled to death.

In those isolated, severe cases of hemorrhagic typhoid fever, epistaxis plays quite an important part. It frequently occurs in young persons, rarely below the tenth year of age, or after the fortieth or forty-fifth, and then almost invariably in persons with predisposing conditions, as *e. g.* chronic alcoholism.

Curschmann[1] has observed epistaxis 110 times among 1,700 cases, or 6.5 per cent.; Liebermeister[1] in 7.5 per cent. of the cases.

When erosions or ulcers of the septum, with simultaneous epithelial abrasion, erosion, or ulcer of the opposite lower turbinated body of the nose, are present in the nasal cavities, synechia are readily formed. These are otherwise, in most instances, artificially produced, through injuries, particularly after cauterizations with the galvanocautery, when they were made, as in former years it was frequently the case, with the flat burner, and the healing process was not duly watched. When the croupy membrane is thrust off, the conditions for the formation of the adhesion are most favorable.

The causes of formation of intranasal adhesions are varied; they may be congenital or acquired, the latter the result of disease or artificial. The nosogenous occur in syphilis, lupus, rhinoscleroma, and acute infectious diseases. No such cases have, to my knowledge, been observed after typhoid fever, but I am in the position to report two such cases:

Case I.—E. H., thirty-five years old, suffered for many years from nasal catarrh and from so-called "inner abscesses" of the thighs, which appeared in 1876 after typhoid fever, and which were operated several times by curetting with removal of the bone. His nasal troubles also dated back to the typhoid. He complained of a raw sensation in the throat, excessive discharge of phlegm from the throat and nose, obstruction of the nasal cavities, and headaches. A fibrocartilaginous adhesion was found in the right nasal cavity, which was thus divided into two separate sections. He was treated in 1878 with irrigations, in 1886 with cauterizations by means of the galvanocautery, and in 1889 90 by nine unavailing attempts at breaking the connections with a forceps. In December, 1890, I broke through the firm adhesions by means of the electric drill, and discharged the patient at the end of two months as cured.

Case II.—E. K., a woman, thirty-three years old, complained of hardness of hearing in the right ear, which was at first noticed during an attack of typhoid fever, contracted in September, 1892, but despite apparent improvement, lasting several weeks, had persisted for two years up to her first presentation. During the typhoid intense bleeding came from the right nostril, lasting the first time about fifteen minutes, and recurred four times, but less severely. The patient, who had never before the typhoid suffered from nasal trouble, noticed a non-offensive discharge, which was intensified for about four weeks after the typhoid, and continued with interruptions up to her first presentation. Headaches appeared once or twice weekly in the right side with dulness over the forehead. There existed also right anosmia and occasional noises in the corresponding ear. The watch was heard in A. D. on pressure only. Examination revealed a chronic catarrhal otitis media and a cicatricial adhesion in the right nasal cavity, between the septum and the lower turbinated body. After removal of the adhesion, the headaches disappeared, the aural noises were considerably relieved, and the hearing power was somewhat improved. The watch is perceived at 1″, the whispered voice at 1′, and conversation at 4′. I would not like to express a positive opinion about the first beginning of the chronic middle-ear catarrh, or rather about its determination, since it probably had existed before the typhoid; at any rate, it cannot be doubted that it was considerably impaired by the typhoid fever, and particularly by its nasal disturbance.

The nasal disturbances in typhoid fever, therefore, consist in dryness of the mucous membranes, abrasion of epithelium, erosion, particularly at the anterior portion of the septum, with occasional, frequently intense and dangerous bleedings. The erosion develops at times into an ulceration, and leads finally also to perforation of the septum. On the other hand, it leads to adhesions with the opposite surface of the lower turbinated body and their above-described sequelæ.

It may be *a priori* accepted that the nasal accessory cavities are affected in typhoid fever. The anosmia in my second case points to an implication of the right ethmoid labyrinth.

Zuccarini[2] found suppuration of the nasal accessory cavities in three cases of typhoid with erysipelas. Siebenmann[3] saw empyemata of the sphenoid cavities in three autopsies of corpses succumbed to typhoid. Harke[4] noted, among one hundred autopsies of adults, sixteen who had died from typhoid fever, and among these, eleven cases with suppuration in the nasal accessory cavities. In two cases all accessory cavities were found diseased; the maxillary antrum alone in two, and with the sphenoidal sinus in two; the sphenoidal alone in three, and with the frontal in one; and the ethmoid with a large perforation of the septum in one case. The causal connection of the suppurations with the acute infectious disease could not be verified in all cases; some positively point to an earlier period.

Grünwald[5] considers the typhoid as the more than probable origin of a case presenting the combination of empyema of the left maxillary and sphenoid cavities. Hajek[6] does not think the near relation between most acute infectious diseases and the affections of the accessory cavities to be firmly established. In influenza and diphtheria only, it has positively, in erysipelas, but probably, the character of the primary infectious disease, while in the remaining infectious diseases the processes of the accessory cavities rather represent the sequelæ of a secondary infection.

The respiratory tract, particularly the larynx, is, in some cases of typhoid fever, the seat of severe lesions, which appear as catarrh, ulceration, and palsies, complicated with œdema and perichondritis; but this is not within the scope of my theme.

Observations on the above-described disturbances are generally few; but they would certainly increase considerably if more attention were paid to the nose and its accessory cavities during typhoid fever. Antiseptic irrigations and powders are to be applied to the erosions, plugging to the bleeding, and the occurrence of adhesions may also be avoided by proper treatment. Discharge of blood in unconscious or sleeping persons into the nasopharynx, when the nose is plugged in front, has sometimes led to death. It is, therefore, advisable to plug the nose in severe cases from the nasopharynx.

Chronic Form of Plague in Rats.—It is not sufficiently recognized in laboratory experiments that a chronic form of plague exists in rats.' From an epidemiological point of view it is of great importance to observe that such chronic infection often occurs. Careful post-mortem examinations on rats, months before inoculated, no matter how, show chronic pathological changes, such as in capsulated caseous nodules in the submaxillar glands, caseous bronchial glands, and fibroid induration of the lungs. In all such cases can virulent plague bacilli be demonstrated, either by culture method or in animal inoculation. Such observations are of the utmost importance for the epidemiologist.

DIAGNOSIS AND PATHOLOGY.

By M. P. OVERHOLZER, M.D.,
HARRISONVILLE MO.

In this age of progress we find, in all the sciences, new methods of work, new and improved ways of approaching and solving problems.

As this march of progress in all scientific fields of labor continues on to higher planes of advancement, we cannot fail to be forcibly impressed with the tendency of the age to discover and utilize more accurate and more practical methods of work. In the great scientific achievements of the present time medicine is no laggard in this field of progress.

Never before in the history of our science have our labors been marked with such a tendency to practical, clinical methods of investigation, practical clinical study of abnormal conditions, and a practical and scientific application of our knowledge in the treatment of disease.

Already many of the uncertain ways of observation and investigation have given way to the more modern and more exact methods of observing and studying causes, conditions, and phenomena of abnormal processes.

Practical clinical medicine is becoming the demand of the age. Speculative theories must give way in the presence of scientific realisms. Clinical facts must take the place of theoretical teachings. Methods of greater accuracy and of more practical every-day utility to the physician must displace the earlier, uncertain, and less scientific methods of investigation and study.

Early in the history of our science medical diagnosis was based most largely upon the clinical history of the disease and a few of the most prominent clinical symptoms.

Later to these means were added the physical signs obtained by palpation, percussion, and auscultation, and more recently to these have been added those evidences found by more exact clinical methods of observation, and a more elaborate study of the minute pathological conditions and processes.

Clinical history of disease, and clinical phenomena as revealed by symptoms, must ever claim their importance in diagnosis. Equally as important and even more so are the physical signs, but in a very large number of diseases it must be conceded that the most important, less misleading, most assuring, and of the greatest aid to the diagnostician are the observable, direct pathogenic factors, and the true pathological conditions. For instance, to diagnose anæmia by pallor of the face, and mucous membranes, vertigo, and dyspnœa is much less positive and less scientific than to ascertain by clinical microscopy and clinical chemistry (or other means) that the blood contains only 2,000,000 red corpuscles per cubic millimeter and only 40 per cent. hæmoglobin. Or by the same means of investigation to learn that the red corpuscles are normal in number, and that the anæmia is due not to a diminution of the red corpuscular elements of the blood, but simply to their poverty in hæmoglobin. Or by carrying our investigations a step farther and finding by microscopical examinations of stained blood specimens that the presence of microcytes, macrocytes, poikilocytes, normoblasts, and megaloblasts reveals to us the fact that the anæmia is of a grave, pernicious form.

To diagnose cystitis by pain in the bladder, frequent micturition, alkaline urine, and an abnormal precipitate is far less complete and much less accurate than to ascertain by microscopical examination that the urine contains polynuclear pus cells in which are found many gonococci, or by further investigation to learn that the inflammatory process is produced by the presence of the colon bacillus, tubercle bacillus, staphylococcus, or some other pathogenic microorganism.

To diagnose malaria by blueness of the finger nails, chill, headache, subsequent high fever, and excessive perspiration is certainly less positive and surely less scientific than to see, by microscopical examination, the living, motile plasmodia in the red blood cells, the crescents and sporules in the plasma, and thus by inspection alone determine positively whether we have to deal with an infection caused by the benign tertian or the pernicious estivo-autumnal germ.

The practical means or methods of investigation in diagnosis of disease which reveals to us most positively and most correctly the pathological conditions and their direct causative factors are to-day the methods that should be used in clinical work.

When pathology first became a part of medicine its teachings consisted entirely of the study of gross pathological changes (gross morbid anatomy). Later came the study of those abnormal changes in diseased structures which are discoverable only by the microscope (pathological histology). Very little reference was then made as to how or why these changes occurred.

To-day the study of the morbid anatomical changes, both gross and microscopical, are only a small part of the work of the modern diagnostician. He must now seek to understand the mode in which these changes occur, the reasons why they appear, the effects they produce, and the results to which they tend.

Thus in the study of disease the etiological factors, the histological changes, the symptomatic phenomena, and the tendency of the disease processes toward recovery or death must all be subjects of investigation and study by the modern diagnostician. A failure of complete bedside clinical examinations is, no doubt, often due to the fact that many medical men spend the greater part of their time in the study and practice of some special part of medical science at the expense and sacrifice, very frequently, of a thorough and practical knowledge of diseases in general. Specialism, of itself, is too wont to consider the needs of one system, or of one organ of a system, at a sacrifice of a study of the whole, losing sight of the great fact that all the organs of the body must work together.

Man, in one sense, is a unit, made up of many parts, and, frequently, especially in medicine, we cannot hope to treat with success a part while ignoring the whole.

The medical practitioner also very frequently fails to obtain a true and full conception of the disease he treats, owing to the fact that his time and interest, in medical work, are confined most largely to the investigation and study of only one, or several parts, and not all of the various processes and phenomena of disease.

To illustrate more fully, one physician may take a special interest in observing and studying the symptoms of the various diseases at the neglect and sacrifice, perhaps, of a knowledge of the abnormal changes producing them (the symptomatologist). Another may spend the greater part of his time and talent in the study of remedies and the application of various measures intended to restrain or correct these various abnormal symptomatic manifestations without a close investigation of their true causation (the so-called therapeutist). Another may take greater interest in the examination and study of the histological changes, the abnormal cellular growths and abnormal reactions of various cellular structures, secretions and excretions of the body at a sacrifice, perhaps, of a close observation and study of the clinical symptoms which these changes produce (the laboratory pathologist and histologist). Another may find himself drifting into that special field of work where he studies the form, habits, life-history, methods of culture, and pathogenic activity of the various forms of microorganisms capable of producing these pathological changes (the laboratory bacteriologist). And still another may observe the symptoms, processes, and results of direct inoculation of these various pathogenic germs in lower animals, and thereby be able to give us valuable information as to the pathogenic activity and the resulting pathological changes caused in living tissue by these various disease-producing germs (the experimental pathologist).

These different fields of labor are all very essential to the progress of our science, and continue to furnish us, from time to time, with vital facts in medicine, but life is too short and the duties in these fields of labor too numerous for any single individual to attempt to carry, into detail, the work of these different important branches of our science.

However, as our achievements of the present time, and all further progress in the future, must ever rest upon a full and complete knowledge of disease in all its parts, we are forced to acknowledge that no medical man can attain the modern ideal of a competent bedside physician without a practical knowledge at least of these all-important branches of our science.

Thus the true physician of to-day, if he would be really worthy of the full confidence of his patrons, complete master of his position, thorough and practical in his work, and attain the eminence of a successful and competent diagnostician, he must be able to play the part, to a good extent, of clinician, microscopist, bacteriologist, and pathologist. Symptoms of disease are simply expressions of pathological conditions.

Pathological conditions must be the result of causes. Causations, alterations, and manifestations are inseparable in pathological phenomena. Etiology, pathology, and symptomatology are links of a chain of factors in disease and its phenomena which are always found united. The physician must ever continue to travel from effects to conditions and from conditions to causes, if he would obtain a full and complete conception of the disease he treats.

In health, in contradistinction to disease, the anatomical structures, the physiological functions, the chemical reactions, and the physical constitution of the various parts of our body are practically normal and undisturbed.

In disease there may be alteration of structure, a disturbance of function, many new and strange chemical reactions, or a change of the physical constitution of the parts affected. We thus have to consider in the study of pathological phenomena, pathologic anatomy, pathologic physiology, pathologic chemistry, and pathologic physics. The means at our command in the study of pathologic physics are inspection, palpation, percussion, auscultation, and mensuration.

The personal appearance, apparent age, temperament, general nutrition, weight, height, vital index, altitude decubitus, posture, gait, expression of countenance, the eyes, nose, mouth, tongue, the skin in regard to nutrition, tone, and humidity, and whether pigmentation, vascularization, anæmia, or œdema is present, and many other facts of clinical importance can be noted by inspection alone. By palpation and the sense of touch the presence or absence of pain or tenderness may be determined, the size, shape, mobility, and immobility of many parts of the body, normal and abnormal, may be ascertained.

The dryness, moisture, heat, coldness, density, and resistance of body structures, also various vibrations—such as frictions fremitus, râles, thrills, and abnormal impulses of many kinds—may be felt.

The methods of percussion and auscultation are simply the practical application of accoustics in diagnosis. Sounds produced in the various normal and abnormal structures of the body by percussion may differ in intensity, pitch, quality, and duration. A change in the normal physical constitution of a part will give rise to a change in these elements of percussion sounds. These changes or variations of sounds from flatness to resonance and from resonance to tympany must be properly interpreted. Regional variations must be carefully studied and the associated physical conditions learned. We must be able to estimate the absolute and relative value of these differences in percussion and auscultatory sounds as indices of tissue change. Correct sound interpretation and the significance of these various auditory sensations produced by percussion and as heard by auscultation, is the secret of success in this part of the work of the diagnostician.

In pathologic chemistry we have another large field from which to gather numerous facts of great importance to the diagnostician. In the chemical examination of the normal and abnormal fluids, secretions and excretions of the body our science has not yet limited the knowledge that can be gained of disease in this field of investigation. In the pathologic chemistry of the urine the presence of sugar, albumin, pus, blood, bile pigment, indican, chromogens, and other abnormal constituents furnish us evidences of various pathological processes of great value.

The absence, deficiency, or excess of hydrochloric acid in the gastric juice, and the presence of lactic acid, fatty acids, pus, blood, etc., are important evidences of pathologic chemistry of the gastric contents.

The percentage of red and white blood corpuscles, serum, hæmoglobin, blood iron, fibrin, mineral salts, the normal or disturbed isotonicity of red corpuscles and plasma, coagulability, the presence of an excessive amount of blood pigments, biliary pigments, biliary acids, uric acid, leucin, tyrosin, xathine bases, etc., are some of the important clinical facts to be ascertained in the chemistry of the blood.

A chemical examination of the exudates, transudates, products of pyogenic inflammation, contents of cystic growths, etc., aid us very materially in our efforts to ascertain the pathology and etiology of many diseased structures of the body.

We shall not attempt to enumerate the unlimited number of clinical facts that can be observed in pathological physiology and pathological anatomy or histology. Without this enumeration we can clearly see that we have many ways or methods of making diagnoses.

To illustrate more fully, we will take for example a case we have not seen—a patient who, we learn, was taken sick suddenly with a chill, fever, rapid breathing, cough, expectoration of blood, and of rusty-colored sputum.

A diagnosis of pneumonia from evidence like this is purely a *symptomatic* diagnosis, or a diagnosis solely from clinical history of case.

We see a second patient who is also taken quite suddenly with fever, no cough, no pain, and no marked acceleration of breathing. We examine the lungs by percussion and auscultation and find dulness over the lower lobe of one lung, diminished vesicular murmur, crepitant râles, bronchial breathing, prolonged expiratory sounds, and increased vocal fremitus. A diagnosis of pneumonia based on such an examination is called a *physical* diagnosis.

A patient with a chronic cough and who expectorates a mucopurulent secretion hands us a specimen of his sputum. We examine it microscopically and find it contains many tubercle bacilli. A diagnosis of pulmonary tuberculosis by clinical evidence of this kind is called an *etiological* diagnosis.

We examine a specimen of urine and find a specific gravity of 1035. By Trommer's test or Haine's test or some other reliable test we find that the specimen contains an abundance of sugar. A diagnosis of diabetes mellitus by this means is called a *chemical* diagnosis.

We examine, microscopically, a thin section of a tumor, and find it is composed of round or spindle-shaped cells of varying size, arranged about large protoplasmic bodies called giant cells, with very little intercellular stroma. A diagnosis of giant-celled sarcoma by this method is called an *anatomical* or *histological* diagnosis.

Differential and direct diagnosis and also diagnosis by exclusion are still other valuable methods that can be used in many cases.

When we take into consideration or use several or all of the different methods of diagnosis which are applicable to a given case, we call it a *clinical* diagnosis.

A full and complete clinical diagnosis, therefore, is the practical application of all the methods of diagnosis, physical, chemical, microscopical, etc., that can be used in a given case. All microscopical, chemical, etiological, and histological diagnoses are usually called laboratory diagnoses.

As these so-called laboratory diagnoses embrace such an important part of a thorough and complete clinical diagnosis, the bedside clinician ofttimes finds his work very meagerly done, owing to the fact that the laboratory facilities are not at hand.

In cases in which the diagnosis is unsettled, or in various complicated cases in which consultation is sought, it is often unsatisfactory to the patient and frequently of but little more satisfaction to the attending physician to be compelled to wait for the consulting pathologist to return to his private laboratory and examine for himself the specimens of blood, sputum, urine, gastric contents, etc., and report on them at some future time.

These methods of practice result very often in an incomplete or incorrect diagnosis at the bedside, as the subsequent laboratory examinations frequently prove. They are not only very often unsatisfactory to the patient and his physician, but such methods of work fail entirely in demonstrating to the attending physician the pathological facts or etiological factors revealed by the clinical laboratory examinations.

Besides, in cases in which the diagnosis cannot be positively made without a microscopical examination of the blood, or a chemical examination of the urine, in which immediate treatment is imperative, delays of this kind may often prove to be perilous to the interests of the patient, as in diabetic coma, uræmic intoxication, septic coma, grave cases of dysenteric, gastric, comatose, hemorrhagic, and algid forms of pernicious malaria, etc.

To overcome this difficulty to a very large extent the writer has devised a portable miniature laboratory-in-hand case for use at the bedside in clinical work.

The same idea has been presented to the profession in this country by Dr. Camac of New York City, who planned a less complete case called the "Camac portable-clinical-apparatus case."

The small portable laboratory, as herein shown, is accompanied with a portable microscope, such as is used by Dr. Thayer in clinical work by the bedside.

By means of this outfit all practical methods of diagnosis by clinical chemistry and clinical microscopy can be made at the bedside of a sick patient.

The portable-clinical-apparatus case is nineteen inches long, sixteen inches high and seven inches wide. Its weight with contents is twenty-nine pounds.

The case of portable microscope is nine and three-quarter inches long, six inches wide and two and three-quarter inches high. Its weight with microscope and accessories is six and one-quarter pounds.

The clinical-apparatus case contains the following list of articles: Stethoscope, stomach tube, ophthalmoscope, hæmocytometer, Tallquivists' hæmoglobin scale, small centrifuge, urinometer, ureaometer, six urinary test tubes, small vial of blue lithmus paper, small vial of red lithmus paper, filtering paper, small funnel, straight-glass pipette, six inches long; curved graduated pipette, with rubber bulb for ureaometer; fine platinum loop on glass rod, coarse platinum loop on glass rod, two pairs of cover-glass forceps, one pair of glass slide forceps, dissecting needle, small lancet, small glass dropper, four culture tubes with culture media for diphtheria bacilli, typhoid bacilli, and various pyogenic microorganisms; one tube of fresh culture of typhoid bacilli for Widal test, two swab tubes, one-half ounce cover glasses, two dozen glass slides, two small staining cups, two concave glass slides for Widal test, one-half ounce Canada balsam, one-half ounce oil immersion, one-half ounce Ehrlich's triacid stain, one-half ounce watery solution methylene blue, one-half ounce carbol fuchsin, one-half ounce of one-half per cent. sodium nitrite solution for diazo-reaction of urine, one-half ounce ferri chloridi for Uffelmann's test for lactic acid in gastric contents, one-half ounce dimethylamidoazobenzol solution, one-half per cent. in alcohol; one-half ounce Lœffler's methylene-blue solution for staining diphtheria bacilli, one ounce Haynes' solution, for diluting blood in glass pipette in counting red corpuscles; one ounce solution for diluting blood in counting white blood corpuscles, one ounce one-per-cent. solution formalin in 90 per cent. alcohol, one ounce sulphuric ether, one ounce nitric acid, one ounce acetic acid, one ounce silver nitrate solution for precipitation of chlorides in urine, one ounce solution for precipitation of phosphates in urine, one ounce Roe's test for bile, one ounce chloroform, one ounce hydrochloric acid, one ounce Haines' solution for detecting sugar in urine, one ounce two per-cent. solution of carbolic acid in water for Uffelmann's test for lactic acid in gastric contents, one ounce stronger ammonia, one ounce bromine in bottle in metal case with screw top, two ounces commercial alcohol, two ounces absolute alcohol, two ounces sulfanitic-acid solution for testing urine for diazo-reaction; two ounces of 40 per cent. solution caustic soda. The case also has room for other solutions which may be desired in other special clinical tests.

The following are some of the most important clinical facts that can be ascertained at the bedside of patient by the above outfit:

Number of red corpuscles per cubic millimeter of blood; number of white corpuscles per cubic millimeter of blood; percentage of hæmoglobin, color index; the presence or absence of microcytes, macrocytes, and poikilocytes; the size of the red corpuscles, whether smaller than normal size (microcytosis) or larger than normal size (macrocytosis); the presence or absence of mononuclear, leucocytosis (lymphocytosis lymphatic leukæmia); a normal or diminished hæmoglobinic tint of red corpuscles indicating a normal or diminished amount of hæmoglobin; the presence of an abnormal amount of fibrin in blood by an increased density of the fibrin network, or fibrin threads in plasma between corpuscles.

The presence of malarial infection may be determined by the following evidences in the examination of fresh blood specimens: (1) By the presence of the plasmodia in the red-blood corpuscles; (2) By an abnormal amount of free vibratory blood pigment in plasma; (3) By pigmented leucocytes; (4) By sporules in the plasma; (5) By the presence of crescents or ovoids or fully-developed gametocytes.

By fixing and staining the blood specimens the following clinical facts can be determined:

The presence or absence of normoblasts, microblasts, and megaloblasts—nucleated red corpuscles found in grave anæmias; the presence or absence of acromatophiles or polychromatophiles; the presence or absence of polynuclear leucocytosis (inflammatory or suppurative leucocytosis); the presence of lymphatic leucocytosis, as found in lymphatic leukæmia; the presence or absence of myelocytes, as found in myelogenous leukæmia; the presence of an abnormal number of eosinophilic leucocytes.

The following are some of the bacteriological and chemical examinations and tests that can be made: The blood serum test, or the Widal test, in the diagnosis of typhoid fever; the detection of tubercle bacilli, pneumococci, staphylococci, streptococci, etc., in the sputum; the presence of these microorganisms and others in the various secretions and excretions of the body. Histologically, evidences of disease may be found by the presence of an abnormal number of alveolar cells from air vesicles of lungs, epithelial cells in urine from tubules of kidneys, excessive amount of squamous epithelium from bladder, shreds of mucous membrane from stomach in gastric contents, etc.

In examination of urine the following chemical and microscopical examinations can be made and the clinical facts as stated below ascertained: Specific gravity and reaction of urine; percentages of chlorides, phosphates and urea; the presence or absence of sugar, albumin, bile pigment, and indican; the presence or absence of the diazo-reaction; the presence of an abnormal amount of uric acid, oxalate of calcium crystals, or other abnormal constituents, as leucin, tyrosin, etc.; the presence of triple phosphates, ammonia-magnesium phosphates, as are frequently found in fresh specimens of alkaline urine in chronic cystitis; the detection of granular hyaline and epithelial casts, pus, blood, gonococci, colon bacilli, tubercle bacilli, streptococci, staphylococci, etc.

In examination of a specimen of gastric contents the presence or absence of free hydrocloride acid and lactic acid can be readily determined.

The case also contains sterile culture with proper culture media for the diphtheria bacillus, typhoid bacillus, and the most common pyogenic microorganisms. We might add other microscopical and chemical examinations to the above list which can be made by means of this outfit, but we think we have enumerated a sufficient number to prove the utility and practicability of this portable laboratory outfit in clinical work by the bedside.

Figure 1 shows the microscope case and the clinical-apparatus case closed with contents inside.

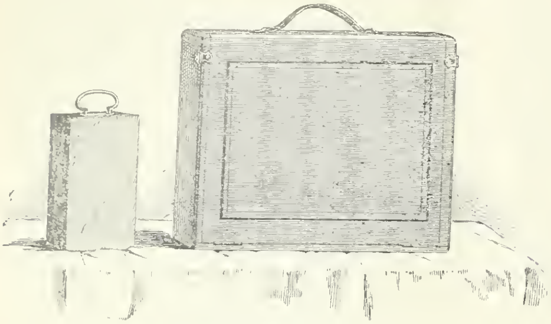

Fig I.

Figure 2 shows both cases open and most of contents on the outside ready for microscopical and laboratory work.

The career of pathology as an applied science in clinical work by the bedside can hardly be said to have more than begun. For years past we have had college pathologists and laboratory pathologists, but the customs and practices in medicine, heretofore, have certainly been at fault in not offering greater inducements and more encouragement toward the permanent establishment of practical methods and proper facilities whereby we can add, more rapidly, to the profession more thoroughly competent bedside pathologists.

The above outfit has been devised and brought to the attention of the profession with a view of taking a step toward the encouragement of a clinical application of pathology in bedside work. It must be conceded that it is of the utmost importance that the study of clinical pathology and laboratory pathology be intimately associated.

In practical work we cannot separate the clinician and pathologist. We trust that these methods of clinical work, as herein suggested, will be a step in bringing closer together the work of clinical medicine and pathological medicine, and by so doing, will aid the modern diagnostician in becoming what is so much desired and so much needed—a practical, clinical, bedside pathologist.

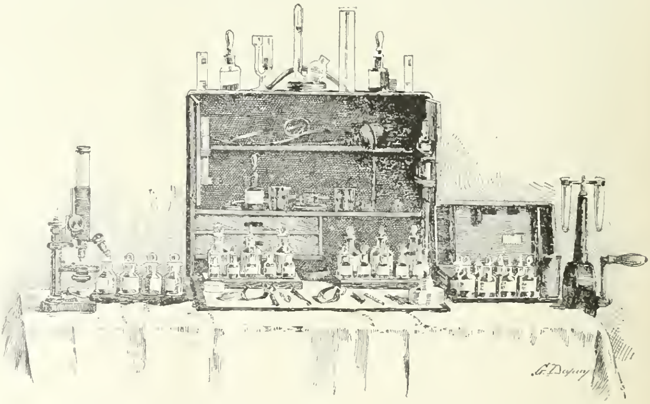

Fig. II.

Rheumatoid Arthritis.—F. B. Hamilton believes that in his own case and three others the cause of the arthritis was spinal irritation. In war time he received a gunshot wound which injured the sixth cervical vertebra, and twenty-one years later he began to suffer, all the joints of both extremities becoming involved. He is a complete wreck. The only three remedies that have relieved his pain (and this they have done for the past two years) are iodide of sodium in ten-grain doses, piperazin, and a tonic composed of quininæ suplh., ferri redact., āā ʒi; ext. nucis vom., zinci phosphidi, āā gr. x; acidi arsenosi, gr. iv; ext. gentian, ʒi. M. et fiant caps. No. 60. One after each meal —*Memphis Medical Monthly.*

A Case of Acute Tuberculosis of the Peritoneum.—Dudley P. Allen reports the case of a young woman of nineteen years, previously in good health, although not robust, who, on April 15, suddenly had a feeling of chilliness and some general abdominal pain, which by evening was referred to the right iliac fossa. The next morning, when admitted to the hospital, her temperature was 103°, pulse 120. The case was diagnosed as one of acute appendicitis, but, on opening the abdomen, the appendix was found to be normal, while masses, resembling tuberculous material, were found studded all over the intestines, and the peritoneal surface of the abdominal wall. A mass was found filling the pelvis posteriorly to the right of the broad ligament, but, on attempting to shell it out, it ruptured, and a considerable amount of yellowish, purulent material escaped. The conclusion was reached that it represented the right ovary, but it could not be removed, and all that could be done was to drain the cavity. The author holds that cases of even advanced tuberculous peritonitis should be operated upon—some of his patients remain in good health at the present time, many years having elapsed since operation.—*The Cleveland Medical Journal.*

The Leucocyte Chart in Pneumonia.—John T. Hewetson concludes, from his researches, that the leucocytosis of pneumonia is due entirely to an increase of the polynuclear finely granular oxyphiles, and probably begins on the first day of the illness. If the patient's reaction is vigorous, and the dose of toxin not overwhelming, the leucocytes increase steadily day by day, reaching their maximum about the day of the crisis. In mild cases, however, the leucocyte curve may anticipate the crisis and commence to fall before that day, whereas in severe cases the leucocytic increase is maintained for several days after the crisis, and then falls gradually. A mild attack of pneumonia gives rise to a mild degree of leucocytosis. A severe attack with vigorous reaction produces a high degree of leucocytosis, and a severe attack with poor reaction produces little or no leucocytosis. It is probable that a falling leucocyte count, as well as an absence of leucocytosis prior to the crisis in a severe case of pneumonia, is to be regarded as a clinical phenomenon of very grave omen. On the other hand, it must not be assumed that every case of pneumonia giving a definite leucocytosis will recover.—*The Birmingham Medical Review.*

TYPHOID FEVER.

THE annual epidemic of typhoid fever, which seems to be upon us earlier than usual this year, is directing attention anew to the mode of extension of this scourge. When the water-borne theory of typhoid fever was first preached, and especially when the late Mr. Ernest Hart lent the aid of his eloquence and enthusiasm to the propaganda, the problem seemed to have been solved, and the tea-kettle policy was accepted as one the general adoption of which would ensure the abolishment, not only of typhoid fever, but of cholera, dysentery, and many other of the plagues of mankind. And, indeed, the installation of pure water supplies in many of the typhoid centers of the continent of Europe did reduce the morbidity from this disease most remarkably. The same result has followed the purification of water supplies or the introduction of filtration systems in this country, and the cities where the disease prevails most extensively at this writing, such as Philadelphia and Chicago, are notorious for dirty water.

But these facts prove only that water is one medium for the conveyance of the germs of typhoid fever; they do not prove that those germs may not be transported by other agencies. On the contrary, they prove that there must be other modes of spreading the disease. In New York City, for example, at least in the Boroughs of Manhattan and The Bronx, the water supply is, for the greater part of the year, above reproach, and even when, in the autumn, the water is tinctured with decaying vegetation and is more or less disagreeable to sight and taste, repeated examinations fail to reveal in it any evidences of typhoid contamination; nevertheless, in the last week of August over two hundred cases of typhoid fever were reported to the Board of Health, and the deaths from this cause numbered more than from any other reported disease, except tuberculosis. In many of these cases the disease was acquired elsewhere, the sufferers having brought the germs with them on returning from their summer holiday, but in others, in those who have not been outside of the city, infection must have occurred here, and otherwise than through the drinking water. Again, in Chicago, where the water supplied to a large part of the city is admittedly bad, the curious fact has been noted that the greatest mortality from typhoid fever is in the district supplied with the least contaminated water. Investigation, prompted by this discovery, has revealed another fact that the disease prevails most in the so-called "Ghetto," where the people are prone to the consumption of raw vegetables, the supply of which comes from market gardens in the suburbs which have been flooded with the overflow from vaults and cesspools.

Other modes of dissemination of typhoid bacilli there doubtless are. The experience of the Spanish war directed attention to the part played by flies in the spreading of infection. Dr. Prudden long ago showed that the specific germ of the disease could be sealed up in ice cut from contaminated ponds and set free with its vitality unimpaired when this ice was melted in the drinking glass, and recently Dr. Veeder has advanced, in the MEDICAL RECORD, very convincing arguments in support of his belief that one prolific source of typhoid infection—possibly a main source in rural districts—is soil contamination.

These and other facts prove conclusively that it is not safe to accept the water-borne theory to the exclusion of all others, and even the boiling of water, while a most necessary precaution wherever the supply is not above suspicion, is not sufficient. Infection through food must be guarded against as well. And, of course, for the sake of others, all discharges from a person sick with typhoid fever must be sterilized before being thrown away. The measures detailed in one of the tracts issued in times of emergency by the efficient Health Commissioner of Chicago, if faithfully executed, would suffice, in a short time, to take typhoid fever out of the domain of practical medicine and make it of historical interest only. These are, briefly: Boil all drinking water for twenty-five or thirty minutes. Pasteurize all milk and cream. . . . Wash your hands carefully before handling any article of food or drink. . . . Wash thoroughly all vegetables and fruit intended to be eaten raw. Wash in water that has been boiled and then cooled. Keep flies out of the house as much as possible. . . . Cover all food supplies, so that flies may not have access to them. Disinfect every discharge [of a typhoid-fever patient]. . . . Sulphate of copper (blue vitriol) is the best typhoid disinfectant—one pound (costing ten cents) dissolved in two and one-half gallons of water. Keep a pint of this in the vessel for discharges from both the bowels and the bladder. Stir thoroughly for a few minutes; let stand for fifteen minutes and the poison will be destroyed."

However the poison of typhoid fever may be conveyed from the sick to the well, we know where it is elaborated, and if the supply of fresh material could be shut off, that already existing—whether in water or in the soil, or floating as dust in the air—would soon become exhausted. The first duty, therefore, of the physician attending a case of typhoid fever, especially in the country and in towns where the sewage empties into a river or is used for fertilizing, is to insist upon the complete disinfection of fæces and urine. In no other way can the community be protected.

Yellow Fever in Spain?—In a despatch from Madrid, under date of September 10, it is stated that a number of cases of a disease having pronounced symptoms of yellow fever have been reported at Pazos Borden, in the Province of Pontevedra.

REORGANIZATION OF BELLEVUE AND ALLIED HOSPITALS.

THE first report of the recently appointed trustees of the above public institutions was handed in for the consideration of the Mayor of New York City on July 1. The fact that these hospitals are in few respects fitted for the work for which they were established has not only been notorious for a considerable period, but for the past two or three years has been widely advertised in journals, both lay and medical. The MEDICAL RECORD has been prominent in making public the conditions prevailing in Bellevue Hospital, and has been especially energetic in the demand that it and its allied hospitals should be placed as quickly as possible upon a proper footing.

The appointment of a board of trustees composed of honorable and trustworthy citizens, whose president, a physician of high repute and wide experience particularly qualifies him for the position—is a step in the right direction, and may be taken as an earnest that radical reforms will be introduced, and that the public hospitals of New York City in place of being a reproach will become a credit to the metropolis of the United States.

In regard to Bellevue Hospital the report says: "Some of the unfavorable conditions we have been able to improve, others, in spite of all our efforts, remain practically unchanged. They can only be remedied, in our opinion, by the erection of an entirely new hospital in the place of the collection of buildings that has borne that name for so many years. The main structure, which contains 718 of the 939 beds of the whole hospital, was erected in 1817, eighty-five years ago. It was used as an almshouse until 1846, when the paupers were transferred to new buildings especially planned for them on Blackwell's Island, leaving this old building to serve as the chief public hospital of New York City. This it has done to this day, and has never been remodeled nor substantially altered from its original design. All the patients must still be received and examined in the one room in the basement, with its poor light and bad ventilation.

"There are between eighty and one hundred applicants for admission a day, and men, women, and children are received into the same room, there being no other available. All varieties of disease and injury follow each other in rapid succession throughout the day and night, and patients must often be transferred to the wards before a proper diagnosis can be made. During the past five months upward of 4,118 ambulance cases alone were brought to the door of this room. Here may be seen the very sick, the intoxicated, the insane, and even those who have been fatally injured.

"Under such conditions the quiet and privacy necessary for a proper and thorough examination are impossible."

Reference is made to the insufficiency of the accommodation of the house staff, there being but sixteen rooms for the forty-three physicians, and to the extremely bad conditions which exist in the quarters provided for the employees. The pay, too, of the "hospital helpers" is shown to be wretchedly inadequate, the result being that the class of help obtained is, as a rule, inefficient and untrustworthy, and is responsible for many of the scandals that have occurred in the institution during the past few years.

The Board of Trustees, feeling the need of more expert observation, called to their aid several of the other departments of the city; namely, the Bureau of Buildings, the Fire Department, the Department of Health, and finally the New York Board of Fire Underwriters. These reports are given with that of the Board of Trustees, and afford further and conclusive evidence of the pressing need of immediate and radical reform in the management and construction of Bellevue and its sister hospitals. The administrative changes of note which have been undertaken by the Board of Trustees are the reorganization of the nursing service and changes in the pavilion for the insane. The responsibility for the nursing of patients in Bellevue Hospital has been hitherto divided between two schools, the New York Training School for Women Nurses and the Mills' Training School for Male Nurses. The former school has had charge of the wards for women and children, and the latter school the wards for the men. The two schools are entirely independent of each other, and each has had its own superintendent. This arrangement is peculiar to Bellevue and has been the source of some of the many evils that have afflicted this hospital. In other hospitals all the patients, men and women, are nursed by women; men being employed in the male wards simply as orderlies to assist in the heavier work. In Bellevue the men's wards have been utilized to train male nurses, no women entering them, except the superintendent of the school. In this the Board consider that the hospital has rendered a service to the public, but has not been quite just to its own patients. The Board believes, as do the Medical Board of Bellevue Hospital and the New York County Visiting Committee of the State Charities Aid Association, that there should be a woman head nurse in charge of every ward in the hospital—except in certain wards—with one or more male nurses under her in the male wards to do such work as is too heavy for women or as can more properly be done by men. These male nurses should receive training as at present, but to secure the best possible nursing service in a ward it is necessary that the head nurse be a woman. The board of managers of the two training schools have become convinced of the soundness of these views, and have decided to place the entire nursing service under the direction of the Superintendent of the Training School for Women Nurses, with assistants to aid her in the instruction and oversight of the pupil nurses, both male and female. This centralization of authority will, it is believed, largely increase the efficiency both of the hospital administration and of the nursing service. Women head nurses have already been placed not only in the male ward of the pavilion for the insane, but also in charge of six other male wards in the hospital, and it is expected that the remaining male wards, with the exception of the male prison ward, the male alcoholic ward, and the male genitourinary wards will be supplied with women head nurses before the end of the year. Male nurses will be trained and graduated as before, but in somewhat smaller classes. Though fewer in number, they will be better nurses, as they cannot fail to profit by the constant oversight of women. The women nurses will also gain in experience, as the male wards contain nearly two-thirds of the patients in the hospital. A committee on nursing, consisting of two members of the Medical Board and two members of the Board of Managers of each of the training schools will supervise the general policy of the nursing service of the whole hospital. The changes in the pavilion for the insane have been on an extensive scale and thorough, so far as was possible. The pavilion itself has been considerably increased in size, and the patients have been placed in charge of an expert alienist.

Mechanical restraint has been abolished, except in cases where it is absolutely essential. Some changes have also been made in the building to permit of a better classification and separation of patients. The bathtubs are about to be removed and replaced by the spray system of bathing, thus doing away with a constant source of danger to the patients from broken limbs and scalding. An attempt has been made, with considerable success, to lessen the overcrowding of the pavilion.

The Board of Trustees recommend the establishment by the State of an acute psychopathic hospital in the city proper. Such institutions have been for many years in successful operation in several German cities, and would undoubtedly fill a long-felt want in New York City.

The report ends with a description of the conditions existing in the allied hospitals, which is, more or less, a repetition, differing but in details from that of Bellevue, and urges in eloquent terms the construction of an entirely new hospital, a new Harlem Hospital, and a new Fordham Hospital, as the only really satisfactory solution of the problem.

New York City, assuredly, should possess public hospitals in keeping with her wealth and advanced civilization; institutions which would be a source of pride to her citizens rather than a slur on their philanthropy and a reproach to their humanity. It is therefore to be devoutly desired that the report of the Board of Trustees may find favor with the Mayor and municipal authorities and be promptly acted upon.

ELEVATING THE STANDARD OF MEDICAL EDUCATION.

The manner in which youths are trained for the medical profession in many parts of the United States has long been a source of deep regret to conscientious physicians, as well as a means of lowering the estimation in which the art of medicine and surgery should be held by the general public.

That 6,000 men or more are yearly qualified as physicians and surgeons in this country is in itself an evil of no small import. The supply is greatly in excess of the demand, but the worst feature of the situation is that a large number of these individuals are incompetent to act as doctors by reason of their defective education. Many medical colleges are conducted entirely upon a money-making basis—the production of a well-trained medical man is quite a secondary consideration—the consequence being that a crowd of persons, badly equipped for the important work before them, are yearly permitted by law to practise the healing art upon the ofttimes unsuspecting and confiding layman.

There are signs, however, that the day of the notoriously inefficient medical college is approaching its end, or, at any rate, that such institutions are coming to be regarded with distrust and suspicion. A strong feeling is now abroad, both among members of the medical profession and enlightened laymen, that a physician before being allowed to practise should undergo tests, sufficiently convincing to show that he is capable of benefiting the community at large and of worthily upholding the honor of his craft.

In the first instance entrance examinations should be satisfying and rigid, and it would be to the best interests of all concerned if a law to this effect were enforced in every State of the Union. A uniform entrance examination for the candidates for the medical profession throughout the country is a necessary primary step, and its adoption would doubtless be followed by the raising of the standard of medical education generally. Several States led by New York, have insisted upon a uniform entrance examination, while others are considering the question. Michigan proposes to establish such a law.

If a law of this nature were made universal—as it certainly will be—most of the superfluous and useless medical colleges must cease to exist, the standard of medical education will be greatly raised, the profession will quickly reach a higher level, and the benefit to mankind will be correspondingly great.

CHRONIC NEPHRITIS.

No disease, not even cancer, has shown a greater increase than nephritis and other forms of kidney affection. Chronic nephritis, or Bright's disease, is obscure in origin, but the causative poison is doubtless initiated by imperfect or perverted action of the tissue metabolism.

The London *Hospital* of August 16 refers to the paper read on the subject by Dr. A. E. Elliot of Chicago at the recent meeting of the American Medical Association, in which he declared his belief that the absorption of toxic material from the intestinal tract plays the most important part in its etiology. The *Hospital* thinks that there is much to be said for Dr. Elliott's contention, and there certainly is this great thing to make one cling to it, namely, that if true, it throws a far more hopeful light upon the treatment of this disease if caught at an early stage, than seems to be cast by other and more generally accepted views as to its etiology. Dr. Elliot points out that when the kidneys fail in their excretory function, the liver cells degenerate, because of the toxic substances which are present in the blood; that the liver then fails to metabolize substances which come to it, and adds its own quota of toxic material to the blood, thus still further irritating the kidney, and that the vicious circle thus formed continually deteriorates the general condition of the patient.

Why kidney affections have increased at so rapid a rate, if Dr. Elliot's theory as to cause be correct, is not a difficult question to answer. The manner in which the majority of the rich and well-to-do persons of the present day live, particularly those in cities, naturally conduces to the conditions arising from intestinal troubles. The greater number of city people over-eat, not to say gorge themselves with rich and indigestible food, and in addition indulge in too much stimulating drink. They are likewise, for the most part, disinclined to exercise; the consequence of this combination of injurious practices and sins of omission being that upon the kidney is thrown the task of excreting toxins likely to hurt its tissue. What wonder then that the ordeal often proves too great, and that the poison permeates the system and widespread degeneration is set up.

If Dr. Elliot be right in his premises, and Bright's disease has its origin in the intestines, the treatment of the malady will be far more easy than if, as many affirm, perverted metabolism be the cause.

The Effect of Weather on the Death Rate.

The London *Hospital* of August 23 has a timely article on weather and mortality. In Great Britain, for the past few months, the weather has been singularly changeable and inclement, and the rainfall has been far above the average.

It would seem reasonable under such circumstances to anticipate an unusual mortality, but, so far as Great Britain is concerned, these gloomy expectations have not been realized; on the contrary, according to the recently issued quarterly report of the Registrar-General, the number of deaths during that period has been less than the average by some 23,000.

The report of the infant mortality is to the same effect the proportion of deaths under one year of age, compared with the birth rate, was 120 per 1,000, the average in the ten preceding second quarters having been 125. The writer in the *Hospital* advances the ingenious suggestion that the lessened death rate during seemingly unfavorable climatic conditions has, perhaps, been due to the greater care that persons have taken to preserve health. Nature has made us to take care of ourselves, and it seems as if we had not only reaped the reward, but as if we might derive therefrom a wholesome lesson for future guidance. It has been uncomfortable to do foolish things in the way of over-fatigue or exposure, and so people have abstained from doing them. Another reason which probably has tended toward the preservation of health, is that in large cities of Great Britain in which the atmosphere is notoriously laden with smoke and other impurities, the copious rainfall has cleansed the air and rendered it more pure and invigorating.

It would be interesting to learn what influence the uncongenial weather to which this continent has been subjected during the past few months has exerted upon the health of its population. If statistics similar to those of Great Britain should be forthcoming, current views as to the maleficient effect of rainy, changeable weather upon the health, may undergo a change, and inclement weather, in place of being regarded as an unmitigated evil, may be looked upon rather as a blessing in disguise.

The Value of Typhoid Inoculation.

Surgeon-Major Wright of the Army Medical School at Netley has recently made an exhaustive report on the results of antityphoid inoculations in South Africa. The medical officers urged at the beginning of the war that the opportunity be given to make extensive tests of the efficacy of the typhoid serum, but Lord Wolseley for a long time refused to permit inoculations, and it was only at the urgent solicitation of Lord Lister that he finally gave a grudging consent.

Professor Wright says that the success of the inoculations was unmistakable, for both the morbidity and the mortality were much less among the inoculated than among those who had refused to submit to the experiment. In proof of this claim he adduces the statistics of the garrison at Ladysmith. According to the summary of the report cabled to *The Sun*, of the 12,234 composing the garrison there, all of whom were exposed equally to typhoid infection, 1,705 submitted themselves to inoculation. In the period from November 2, 1899, until February 2, 1900, there were 1,489 cases of typhoid among those who had not been inoculated, and only thirty-five among those who had been inoculated, instead of about 250, which would have been their due proportion. There were eight deaths among those who had been inoculated to 329 among those who had not been inoculated. The death rates of the two groups were respectively .047 and 3.12. As a result of the diminished mortality, superadded to the diminution of incidence of the fever, is is claimed that the reduction of mortality from typhoid amounted to a fourfold reduction.

These statistics are, doubtless, comforting and cause the hope that the mortality from this scourge of armies may be reduced, but it must be remembered that the experiments cited were made upon soldiers in garrison and not on the march. Men who are marching under a burning sun in a hot and dry country will drink any water they see, no matter how polluted it seems to be or is, and not even military discipline will make them cherish their thirst for the twenty or thirty minutes needed to boil the water so as to make it safe. And again, even in garrison, the men who had enough faith in medical science to submit to a protective inoculation would also be much less disposed to disobey the sanitary injunctions laid upon them than would the careless or sceptical uninoculated.

The Philippines Health Problem.

Mr. James A. LeRoy, secretary to Professor Worcester of the late Philippines Commission, writes in the *Outlook* of July 26 on the above subject. As secretary to the said Commission, Mr. LeRoy enjoyed exceptional opportunities for gaining an accurate knowledge of the matter on which he discourses.

The occupation of Cuba has been of inestimable advantage to that island, so far as sanitary affairs are concerned, and although the situation in the Philippines in this respect is a much more complex one, yet corresponding benefits will doubtless be conferred on the inhabitants of the United States' far eastern possessions by the advanced hygienic methods introduced by American army medical officers. Mr. LeRoy pays a well-deserved tribute to the energy and executive ability displayed by these men, and recounts, at some length, the various schemes devised by them to fight successfully against disease.

In July, 1901, executive authority was transferred to civilians' hands, and military orders were replaced by organic laws for all provinces under civil control. Under these laws there was begun the organization of provincial boards of health, and of municipal boards as well, wherever native physicians could be found to lead them, responsibility for public health work thus being distributed, with centralized control in the general board at Manila, which is under the Department of the Interior, the president being Major L. M. Maus, temporarily detailed, and in which the native element also finds representation. Professor Paul C. Freer was summoned from Ann Arbor to organize a centralized plan of laboratories, chemical, and biological, for the making of virus, etc. Laws for the regulation of the practice of medicine and surgery, and of pharmacy, for compulsory vaccination, regulating the manufacture of alcoholic beverages, and others of like nature, were passed and put into execution. The combating of rinderpest, which had already destroyed in some provinces 75 per cent. of the draft animals, was carried on; and a campaign was inaugurated against the plagues of locusts, which have, periodically, for centuries scourged the islands and reduced regions to the verge of famine, a fungus disease being imported from South Africa and introduced among the flocks of locusts in province after province.

Rats have been killed on a wholesale scale. A vigorous campaign of vaccination has been carried on, and a strenuous war has been waged against cholera.

With regard to the lack of physicians in the Philippines, Mr. LeRoy has this to say: "Except for the comparatively few educated in Europe, to be found in the most important cities, the native physicians got their equipment at the friar-directed college of St. Joseph at Manila." Editions of the "standard" authorities in use there date back to 1845; the teaching of anatomy is a farce, and, it is said, no female cadaver has ever been dissected there; until within the past few years bacteriology was not taught at all, and, unless they have been bought very recently, it is now taught without microscopes. Comment is superfluous.

That benefits of no mean order have been gained through the American occupation of the Philippines is shown by the very considerable decrease in the death rate of Manila—wholly due to the energetic action of those responsible for the sanitary supervision of the city.

As time goes on, a further improvement in the general health of the inhabitants of the Philippines under American control will surely be manifested.

News of the Week.

New Hospitals Needed.—The report for the five months ending June 30, of the Board of Trustees of Bellevue and allied hospitals, of which Dr. John W. Brannan is president, has been made public. It contains much information of a most startling character to the greater part of the community, both lay and medical, though to those familiar with the public hospitals of the city, and especially with Bellevue, the facts set forth in the report have long been known and deplored. Among other defects at Bellevue, referred to by the Trustees, are the inadequate facilities for the reception of and examination of patients, the overcrowded sleeping rooms of the house staff, the dark and unwholesome quarters of the employees, the indecent condition in the prison wards, the unsatisfactory methods of cooking and serving the food of the patients, and the antiquated and insanitary character of the plumbing throughout. The prison wards are in the basement. The men's ward is about 40 feet long by 20 feet wide and 8 feet high, with two windows on only one side, giving about 500 cubic feet of air to each of the thirteen beds, the minimum exacted in the tenement-houses by the Board of Health being 600 cubic feet. In summing up their views the Trustees assert that there is but one remedy for the conditions set forth, and that is the construction of an entirely new Bellevue, a new Harlem Hospital and a new Fordham Hospital. A new Harlem Hospital is already assured, the site having been purchased and an appropriation for the new building having been approved by the city authorities. Certain steps have also been taken toward the erection of a new Fordham Hospital, the State Legislature having at its last session passed a bill authorizing the expenditure of $500,000 for site and building. The need for a new Bellevue is even more imperative, and as the construction of a hospital of such a magnitude, will necessarily extend over several years, the report urges that it be authorized at once.

About the same time that this report was published, Mayor Low issued a "talk" on the Health Department, in which he virtually pledged his administration to increase the number of hospitals for the treatment of contagious diseases, and to provide for the purpose a fund of $2,000,000, to be expended in the next three years. After commenting on and commending the official labors of Health Commissioner Lederle, he pointed out the great need of the city for more hospitals for treatment of infectious diseases. London, he said, has 6,500 beds, or one for each 1,000 of population; New York has only 750 such beds, one for each 5,000 of population. New York, through an issue of bonds this year, is adding 225 beds. In New York only nine and one-half per cent. of cases of infectious diseases are treated in hospitals, and the Mayor believes the city can no longer afford to neglect this great element of safety.

A synopsis of the general plan for the new hospitals by Mr. R. C. W. Wadsworth, secretary to the Commissioner, is given in *Charities.* It is planned to devote the hospital on North Brother Island to smallpox patients and convalescents. This arrangement will relieve the wards of the other hospitals. Much preliminary work has already been done on the island. A nurses' home and a sun parlor for convalescents will be erected

The most important step planned is the erection of a large hospital for the treatment of scarlet fever. This will be at the foot of East Sixteenth street, will be six stories high, and will be, possibly, the largest hospital in the world for the treatment of scarlet fever. A disinfecting plant will be constructed, a laundry, a new morgue, ice plant, electric lighting plant, and storehouse. In order to meet the immediate demands in Harlem a disinfecting plant will be established there also, and a tract of land will be purchased for the erection of a hospital. At the Kingston Hospital in Brooklyn additional pavilions will be erected and the Sinking Fund Commission will be asked to provide funds for the purchase of adjacent property. The low ground on which the present buildings stand will be filled in, and the new buildings will be erected on the more elevated site adjoining. A nurses' home, electric lighting plant, and ice plant are also planned. Separate hospitals for the treatment of contagious diseases, smaller but complete in detail, are planned for the Bronx, Queens, and Richmond. A disinfecting plant is already erected on the present poor farm, in the center of Staten Island. These borough hospitals will not maintain forces of nurses and employees the entire time. With but one or two cases to deal with, the expense would be less to transfer patients to the Manhattan institutions. But the borough hospitals will stand in readiness in case of an epidemic.

Closure of a Medical College.—It is announced that the Cincinnati College of Medicine will not reopen this autumn, the reason for this being that the new State law requiring a rigid entrance examination has reduced the number of students below the limit necessary for the support of the institution. Other States are falling into the procession led by New York in demanding that their medical graduates shall possess a decent general as well as professional education, and just in proportion as the procession lengthens so will the number of medical students diminish. But with reduction in quantity will come improvement in quality, and so the standard of the profession and the standing of the practitioner will be raised, widening the chasm between the qualified medical man and the quack, until even Mark Twain will be able to distinguish one from the other.

Discontent in the Bellevue Training School.—The members in the junior class of the Bellevue Training School for Female Nurses are said to be circulating a petition which will complain against the rules of the institution as set down by the new superintendent. One of the most objectionable of these rules, and it is believed the main cause of the discontent, provides that the students shall speak to the physicians and male nurses only on matters of business, and shall hold no conversation whatever with them outside of the hours of duty.

A New Method of Sex Control.—An ingenious Russian official, in command of a Cossack station near the Caspian Sea, has invented a method of sex control, which threatens to rival that of the late Professor Schenck. Being anxious that his district should make a good showing in the matter of boy babies, this consistent underling of the most paternal of governments has decreed that henceforth none but male children shall be generated in the country under his command. In order to make this law effective, he has ordered that the father of every girl baby born in the district shall be punished with fifty lashes with the knout. The veracious correspondent who sends this story to a London paper adds that already several men have received their fifty strokes for failure to comply with the law.

Compulsory Vaccination in France.—A law has recently been enacted in France making it compulsory upon parents to have their children vaccinated during the first year of life, and upon all persons to be revaccinated at the age of twenty-one or within one year thereafter.

Cholera on a Transport.—The transport *Sherman*, which was quarantined for ten days at Manila, arrived at Nagasaki on September 11 with four cases of cholera on board. There were three deaths during the voyage from Manila, and the transport was again quarantined. This is the first time cholera has appeared on a transport after the period of detention at Manila had passed and the ship had been allowed to sail.

Bequests to Philadelphia Hospitals.—By the will of the late Miss Harriet S. Benson, who was regarded as the richest woman in Philadelphia, and had been known all her life as a philanthropist, bequests were made as follows: $10,000 each to the Homœopathic Hospital, the Children's Hospital, the Home for Incurables, the Philadelphia Orthopedic Hospital; $5,000 each to the Pennsylvania Hospital, the Philadelphia Polyclinic, the Medico-Chirurgical Hospital, the Pennsylvania Training School for Feeble-Minded Children, Howard Hospital and Infirmary, Wills Eye Hospital, Hahnemann Medical College, Women's Hospital, Gynecean Hospital, Maternity Hospital, the Women's Homœopathic Hospital, the Children's Homœopathic Hospital, and St. Luke's Homœopathic Hospital.

Expensive Smallpox.—The village of Ossining, N. Y., had three cases of smallpox last summer, and treated them on a houseboat in the river, which was hired at a cost of $225. The launches, towboats, and other craft required to convey the doctor and others to and from this boat cost $325. The provisions cost $375, including $125 for whiskey for the three patients. The bill of the physician, who made fifty visits in twenty-five days, was $2,000, and a number of nurses and attendants expect to be paid at the rate of from $5 to $10 per diem each. In addition, there is a bill of $180 for clothing, and sundry claims for damages, which the village trustees are called upon to pay. Such, at least, is the report of the cost of the outbreak, which was published in the daily paper, and the cost seems rather great.

Major Ronald Ross Coming to America.—A despatch from Liverpool announces on the authority of Sir Alfred Jones, president of the Liverpool Chamber of Commerce, that Major Ronald Ross of the School of Tropical Medicine, and formerly of the Indian Medical Service, who has done so much for the sanitation of many of the malaria-infected regions of western Africa, is shortly coming to this country in response to an invitation to investigate malaria.

Backsliding Cuba.—It was reported in the papers one day last week that the employees in the Sanitary Department of Santiago de Cuba had struck work. The streets were no longer swept, and no rubbish had been moved for two days. The cause of the strike was that the men had not been paid for two months. The city is said to be in a filthy condition.

The Unification of Heroic Remedies.—Of the several congresses of an international character, held in Brussels this month and last, not the least important is one which met this week. Its object was to arrange a standard of strength, to be followed by every national pharmacopœia, for preparations of the most powerful drugs, such as aconite, digitalis, belladonna, etc. At present there is such a diversity in this regard, that in the case of some drugs the maximum dose of a preparation made after the directions of one pharmacopœia might prove fatal if a preparation of the same name, made according to another pharmacopœia, were substituted. The delegate to this congress from the United States was Dr. Horatio C. Wood of Philadelphia.

The Lane Medical Lectures.—The seventh annual course of these lectures were delivered at the Cooper Medical College, San Francisco, during the last week in August, by Mr. C. B. Ball, Regius Professor of Surgery at the University of Dublin.

Obituary Notes.—Dr. EDWARD B. VANDYKE of Philadelphia died at Sunset Point, Rock Hill, N. J., on August 31, at the age of sixty-seven years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1856.

Dr. J. FRANCIS HAMILTON died at Philadelphia on September 1 at the age of thirty-two years. He was graduated from the Medical Department of the University of Pennsylvania in 1893, and was visiting physician to St. John's Orphan Asylum.

Dr. WM. J. WENTZ died at New Providence, Lancaster Co., Pa., on September 5 at the age of sixty-four years. He was a graduate of Jefferson Medical College in the class of 1865, and one of the organizers of the Lancaster County Medical Society.

Dr. WM. O. XANDER died at Philadelphia on September 7 as the result of injuries received in being thrown from his carriage by the running away of a horse he was driving. He was a native of Carbon County, a graduate of Palatinate and Ursinus Colleges, and of the medical department of the University of Pennsylvania in the year 1895. He was thirty-five years old.

Dr. CHRISTOPHER M. BELL of Newport and New York died at Baden-Baden, Germany, on September 3. He formerly practised in this city, but of late has resided at Newport. He was traveling with his wife for recreation at the time of his death.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

QUESTIONS RELATING TO PUBLIC HEALTH—LOCAL GOVERNMENT BOARD'S REPORT—AN EXACTING NURSE—TRANSACTIONS OF THE TUBERCULOSIS CONGRESS—"BRITISH ACADEMY."

London, August 29, 1902.

Sir C. Cameron's address, briefly mentioned in my last, was delivered in the Section of Preventive Medicine and Vital Statistics of the Royal Institute of Public Health, the annual meeting of which has just been held at Exeter. Besides the point I noted, Sir Charles said he thought it would be announced that the experiments in Essex completely negatived the theory of Dr. Koch. It did not seem to be thoroughly established that human and bovine tuberculosis were distinct diseases. Was it possible that the bacilli of man might be identical with those of cattle, though not so potent? Until we had further and absolutely reliable information sanitary authorities would not be justified in permitting the sale of the flesh of animals which were seriously affected, or the milk of cows which had ulcerated udders. He also pointed out how typhoid was caused by a polluted condition of the soil, and said legislation was needed to prevent pollution of oyster-beds and similar places. He also expressed the opinion that new clothes should be sterilized before being worn, as it was proved that they might become infected with scarlet fever, measles, smallpox, or other diseases whilst being made.

In the Veterinary Section, of the same Congress, Mr. Eaton Jones read a paper on Veterinary Supervision in the Housing of Domestic Animals. He said the first care of the veterinary surgeon was to see whether the patient was affected with a disease likely to be injurious to the community—anthrax, rabies, foot and mouth disease, sheep scab, swine fever, tuberculosis, and so on. He then discussed the housing of animals in relation to their health, and that of persons connected with them. His excuse for detailed remarks on this subject was the deplorable state in which he had seen stables and cow-sheds. He needed no such plea, for I think most people have seen animals, particularly cows, huddled together as closely as they could be packed, with no ventilation and no drainage worth the name. The paper was well received and elicited commendatory remarks. The president said the institute was anxious to secure a closer alliance with veterinary surgeons.

Mr. P. G. Bond, M.R.C.V.S., then read a very interesting paper on the "Genesis of Smallpox." He mentioned the old pathological error of the malignancy of cowpox as due to its being confounded with cattle plague. He mentioned, too, that Benjamin Jesty inoculated for cowpox in 1774, which was twenty years before Jenner began his experiments. Other papers on vaccination were also submitted to this congress.

The subject of housing of the working class was taken up with vigor, and, after discussion, a resolution was adopted urging the government to give effect to the recommendation of the Relief Committee.

Another resolution adopted was in favor of appointing a minister of public health. This question was raised in a paper by Mr. Poyntz Wright, which met with considerable support. I do not, however, expect the government will be influenced by the opinions elicited, for the proposal has been urged from time to time, for I know not how many years. Much as there is to be said in its favor, there are some objections, and much as the medical profession would approve, there is no likelihood of the public supporting the plan. Unfortunately, the public is very distrustful of sanitarians—perhaps I should rather say, a section of the public—and any movement in that direction is thought to be costly.

The Local Government Board is our central sanitary authority, and has hitherto "muddled along" with a fair amount of success. But that Board is really a collection of so-called departments, of which the Medical Department is one, and, I fear, by no means the most influential. All that the Board has done to advance public health has been at the instigation of its chief medical officer, and perhaps the Board deserves credit for its admirable selection of the successive holders of that important position.

I fully agree with the Royal Institute that a completely organized ministry of health would be advantageous, but I have little hope of seeing it established within a reasonable period. The great minister who raised the cry *Sanitas, sanitas, omnia sanitas,* had no notion of so practical a result, and his followers have displayed no more zeal for sanitation.

There is one point worth noting in the sympathy felt for the plan. Some people seem to fancy that if a minister of health were appointed he would be an eminent medical man with great sanitary experience, such, for example, as the chief medical adviser of the Board They may give up the illusion. Any such office would go to a political placeman. Governments of all parties have no idea of conferring the best offices on those best fitted for them. If a mere doctor must do the work he must be engaged as a subordinate. The figurehead will have to be a hanger-on of party, who, whatever his qualifications, has to be provided for in some place—and that figurehead will draw the chief salary. The way in which, as I told you, the Registrar Generalship was lately filled up should disillusionize those who think a health minister would have to be a doctor.

The report of the Local Government Board for the year 1900-1901 has appeared. It is the thirtieth annual volume and contains, as usual, the report of the medical officer—Mr. Power. This only occupies twenty-six pages, but it summarizes the work of his staff and introduces their own reports, which are worthy of their predecessors. Vaccination, plague, and other subjects have served to keep the staff alert, and their scientific investigations are of great importance to the community and of interest to the profession.

The committee of a hospital at Swansea have resolved that the staff shall not publish a report until it has received their sanction. What next?

The nurse who prosecuted Dr. Cullingworth for performing an operation on her which she alleged to be unnecessary, has sought the advice of a magistrate because, as she says, she cannot get admission to a hospital for the purpose of having an operation performed, which she told the magistrate was necessary. She did not tell him of her former litigation, nor on whose opinion she now relied.

The *Transactions* of the Tuberculosis Congress held here last summer have now been issued in four bulky volumes. It is well, perhaps, that the proceedings should be authoritatively recorded, although very full reports were given by the journals at the time—your own being in no way behind those on this side.

The "British Academy" is henceforth to be reckoned among our learned societies. It is established to promote historical, philosophical, and philological studies. The King has granted a charter to forty-nine distinguished persons, constituting them the first Fellows of the new body. You will notice that neither science nor pure literature is comprised in the academy. But science has the Royal Society and the British Association, besides the numerous bodies devoted to its various branches.

VIRCHOW.

To the Editor of the Medical Record:

Sir: Virchow was the greatest and grandest intellect that has as yet appeared in the human arena. That reads dogmatic. Men generally look on greatness in the individual in direct proportion to the benefits they or the race receive through him. Of that side of Virchow's life-work eulogies enough will be written. The endeavor here will be to make an etiological study. In doing that Virchow's weaknesses will also be considered. By considering them, the greatness will only be more apparent. Virchow's greatness is not only manifest in his contributions to medical science, but in his many-sided intellectuality. His greatest work is undoubtedly the enunciation and manifestation of the biological law of the phylo-ontogenetic evolution of living things, and its demonstration in man. *Omnis cellula e cellula.* A great weakness was Virchow's inconsistent denial of himself in his opposition to evolution, of which he was perhaps the greatest exponent. While nearly all men to whom the world has given the crown of greatness were really great in one thing, Virchow was great in many things. His greatness was encyclopedic, but his greatest bigness was his humanitarian broadness. All that pertained to the intellectual, social, and political betterment of man found in Virchow an earnest and doggedly persistent student and advocate. "Doggedly persistent" describes one of the master's strongest characteristics. He was not an enthusiast of the emotional type. Interested though he was, cold-blooded persistence in doing marked him. His clearness of intellect, his logical philosophy, his endless detail in investigation, his unwearying industry, could only come from dogged persistency. With no flippancy he might well be termed the "bull dog" of the scientific arena. Who could work with him? Four hours' sleep was the maximum he allowed himself in his active years. It is said of him that he frequently dictated to four note-takers on four different subjects; for instance, a pathological article, a political polemic, a paper on drainage, and an anthropological dissertation at practically one and the same time, dictating to one scribe and then to the other until he came again to the first, and never asking either "what did I say last?" but taking up each subject as if he had been continuously on that one subject. Woe betide the unfortunate who was not ready for him when his turn came, for Virchow was an unreasonably impatient man, as all such workers must be. He was the terror of candidates for examination, especially the "Kreis-physicus" aspirants. In this regard the following is an example: Such a candidate, after waiting long for Virchow's appearance—non-punctuality was one of his weaknesses; Virchow waited for no one, while all had to await his pleasure—and anxiously viewing the cadaver in that dreaded "Examen Zimmer," was met by Virchow as if blown through the door by a cyclone. Without any greeting, the master ordered, in no gentle voice, "Fangen sie an" (begin). The poor candidate stood before the cadaver trembling with anxiety, knife in hand, but not a movement, the perspiration flowing almost in a stream. "Come, come, begin," snapped his autocracy. Not a word, but a gasping mumble. "Speak Greek, speak Hittite, speak Latin, French, German, English, speak anything, but don't stand there like an automaton, mumbling 'm, 'm, 'm. "Donnerwetter, Mann, haben sie keine Zunge?" was the encouraging greeting. The result need not be described.

Slight though he was, Virchow had an iron constitution. That much he owed to his Pomeranian ancestry. A critical study of Virchow's ancestry and posterity, as of many another of the world's great ones, is of interesting value. In the descendant sense, Virchow was a "freak," a "lusus naturæ"; one might say a "lapsus" in the geneological tree. We read of no marked genius in his family history. Certainly none has made its mark to any degree in descendants. It is most often so. This is not to the credit of man's intelligence. The children are insignificant; the world, in its ignorant injustice, makes them feel it in comparison with their sires. We do better with our horses, cattle, and pet stock. In the human family winning producers are the rarity. The exception of continuing ability of the genius order in families proves the rule of man's ignorant self-reproduction.

The unthinking say that such men as Virchow are "self-made." "Ignoribimus," as Haeckel would say. "Nonsense," in plainer English. Virchow was made to be what he was at the moment of the contact of the paternal spermatozoon with the maternal ovule. Virchow himself did nothing. Speaking again, in this connection, of his greatness, the world knows of but one greater scientist, the greatest of all in his profound generalism, "Man was made from the dust of the ground." Scientists, *per se*, have ever since been trying to trace the origin of the dust, trace its course, and answer the negro sceptic's question "how far de dust stick togedder." Virchow has done more than any one else to show us how it stuck "togedder" in his "Law of Cellular Evolution." "Man Is a Cell-state," said the master. Certainly a grand state of the dust was manifest in the man Virchow. He was the voice of the dust as it was present in the atoms of his cerebral molicules. "Self-made!" Away with such ignorance. The truth is that the dust took the bit of genius in its teeth and ran away with the man Virchow. It does the same with the fool, with the brainless descendant of genius, when human ignorance has not stuck it together in the same way. Virchow "self-made"! Few realize that conditions, political environment, had far more to do with the making of Virchow, and European scientists in general, than he had himself. It might be said that these conditions found Virchow not "self-" but ready-made. Is any one insane enough in his Americanism to think that the Pomeranian boy Virchow, with his few environmental advantages, would have become the world's greatest in the environment of the United States? It would be as rational to think of a J. Pierpont Morgan becoming another of the world's greatest if born of native parents in Patagonia. Who thinks, though an apparent truth, that Virchow and others in Europe really owe their greatness to the necessities of the national struggle for existence and individuality among the nations of Europe? Brutal though the words appear, the assertion of a European thinker that the chief duty of patriotic citizens is to prepare food for cannon is true. It is to take care of the "cannon-food," to see that it is well-bred physically and developed mentally, that it, itself, is well fed, well clad, well provided for, that all its resources are stimulated and cared for, that is not only the first necessity of European governments, but the chief cause of the recognition and success of Continental scientists. There every man counts as a national defender, and every woman as a defender-producer. There science is encouraged and supported because the results of investigation contribute to the national solidarity and its surviving power the resources of the nation, human, animal, and industrial, even more than any other factor. Such a man as Virchow is worth more to a European nation than its entire standing army. Not only are such life-preservers in the broadest sense, but they do more to develop and sustain the industrial nation—preserving armamentum—than any other factor. One has only to think of the discovery of the anilin dyes, of the hygienic work of a Virchow, Koch, or Pasteur, to realize the force of national self-preservation in the support of science, to realize how little its votaries are really self-made.

Such men would be dead geniuses in the United States, "dead to the world" as Crusoe or Juan Fernandez, Paternal governments, represented by intelligence, are, generally, not the curse to their people that those of indifferent and corrupt republics have thus far been in the history of the world. War, national struggle in that sense may be a curse, but thus far in the history of men it has done far more for the advancement of the world than peace. Peace is death, war is life, even if it kills so many of the living. War does not make Virchows, but thus far in the world's history its necessities have called them forth and made use of them. Competition is war, and not until industrial and social competition begins to arm itself in verity for the struggle for existence will genius be recognized by the people and put in the saddle of government, that a truceful peace may control the storm that men may survive and struggle without the last resort to cannon-food and murder. Without war in some form there can be no seeming peace, no science, and no civilization. Forget it not, the imminence of war, the national struggle for existence, made Virchow, not he, himself. The imminence of industrial and social war may yet make such men in this country. Forget it not, the struggle to be a nation made this country as it made Washington, Hamilton, Adams, and those we honor as great, what they were. War made Lincoln, Grant, and Sherman, not peace.

Virchow's inconsistent opposition to evolution has been noticed. There is a greatly mistaken conception regarding evolution, even among scientists. The course of evolution is confounded with the thing itself. Evolution, *per se*, stands for the formative, individuation facts in nature. The course taken is another matter. Evolution does not stand for perfection. In what we term nature there is really no purpose, no law. The course of evolution has been from simplicity in formation to complexity. In point of fact, from the simple molecule to the complex, the acme of complexity being the molecule in the brain of such a man as Virchow; from the simple-celled organism, uniting in itself all the essential attributes of the most complex; it can maintain itself, grow, and reproduce itself, as perfectly, according to its nature, as the most complicated machinery in the most complex organism of man. There is no such thing as perfect and imperfect in nature. Those terms simply imply our conception of adaptability. Death is as perfect a representation of dissolution, or individual involution, as life is of biological individuation, or evolution. Health is as perfect a representation of physiological individuation as death is of pathological dis-individuation.

Virchow's opposition to evolution is probably the result of his greatest weakness, for how could the author and exponent of "Omnis cellula e cellula" be an anti-evolutionist? That weakness was vanity, and its twin sister, envy. His susceptibility to flattery is well known. He hungered for it. Great as Virchow was he could not stand greatness in another in his particular field. It was long ere he could think or speak favorably of Robert Koch. He was rudeness itself to other distinguished members of the Berlin medical faculty. He was constantly jealous of his prerogatives as head of the Pathological Institute, and made clinicians of great repute feel it if they wanted to see the microscopical results in their own patients. He was envious of the reputation of Darwin, and hence his opposition to evolution. While there certainly were not two Virchows in the medical world, Virchow would not admit the possibility of their being another in some kindred branch of science. In this regard Virchow's reputed remark of Gerlach, the greatest man veterinary medicine has yet seen, director of the Veterinary College, that "there was but one Gerlach in the world, and could never be a second," is characteristic. With dead men it was different. He delighted to honor greatness in the dead. Above most men he lived to enjoy his own greatness. He was terrifically autocratic and jealous of his authority in most trivial things. Like many Germans, he believed in muffling and protecting the throat. On one occasion a person working in his laboratory happened to have a slight acute laryngitis. Virchow, noticing it, attributed it to the person's wearing very low collars, and recommended standing collars, such as he wore. The person not procuring one, Virchow got him one, and insisted on it being put on then and there. The man not having it on the next day was severely "called down" before the class, and it was weeks before Virchow got over the "insult" to his dignity, and treated the man decently. His plastering his hair down with grease was an insignificant though striking illustration of weakness in one so great. An amusing and often dangerous vanity was his conceit that he thought himself a great physician as well as pathologist. Any one who has worked under him for years can remember his escapes from Virchow's surgical skill if happening to have anything approaching a furuncle visible on his person. Virchow would insist on opening it, and grasp an autopsy knife, perhaps from the man's hand. His indignation at not being permitted to use such an instrument was amusing, as well as instructive. His Pomeranian friends coincided with him in the idea that he was a great physician, and those about him were often amused at the visitations he received from his learned friends for consultation and treatment. His prescriptions belonged to the complicated wonders of the Dark Ages in medicines that led to the revolt of Hahnemann.

One of the greatest characteristics of the German government was the manner in which it recognized Virchow's abilities and honored him with trustworthy positions, even though one of its greatest opponents politically. It takes real greatness to recognize ability in a determined opponent. Bismarck never had a more obstinate one than Virchow in many of his pet schemes, yet he never failed to send him on important missions when the occasion required. The anecdote of Bismarck's challenging Virchow to a duel and the latter's acceptance if Bismarck would agree to his choice of weapons, to eat a pound of raw trichinous pork, is characteristically amusing, whether true or not.

FRANK S. BILLINGS, M.D.

SHARON, MASS.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 11, 1902

The Symptoms and Treatment of Hepatic Cirrhosis.—George G. Sears, from an analysis of seventy-eight autopsies, draws the following conclusions: Hepatic cirrhosis is, in a majority of instances, but one expression of the effect of a systemic poisoning. The degenerative changes in other organs are to be regarded as part of this general process, rather than as complications. The splenic tumor and dilated veins are due in part to portal obstruction, but also seem dependent on the underlying toxic cause, since they are occacionally associated with slight hepatic changes. Dilation of the vessels may have some effect as a compensatory mechanism, but is rarely adequate to prevent ascites. Persistent jaundice and hemorrhage from the digestive tract seldom occur until the connective tissue formation is well advanced. Hemorrhage was found to be almost invariably due, when a full pathological description was given, to some gross lesion, which in most cases was an œsophageal varix. Ascites occurred in practically the same proportion of cases in all four classes, and was a late symptom. Its early appearance was, with rare exceptions, associated with some form of peritoneal inflammation. Continuous fever was never found, except in the presence of complications. A brief elevation of temperature occasionally occurred, for which no cause could be discovered. No evidence was found to show that the course of the disease was not always progressive, but a high grade of cirrhosis was sometimes reached without incapacitating the patients. Surgical treatment may be indicated in a very small proportion of cases, but conclusive evidence is still lacking to show that the ascites in the cases successfully operated upon was due to hepatic cirrhosis and not to coincident conditions.

Cirrhosis of the Liver in Childhood.—John Lovett Morse says that all the forms of cirrhosis which are met with in adults occur also in childhood. In addition there are several forms which are peculiar to children. The symptoms of cirrhosis in childhood are the same as in adult life. So also are the pathological changes. It is not a common disease in childhood, but perhaps less uncommon than has usually been thought. The ordinary forms are found most commonly between nine and twelve years. The form due to obliteration of the bile-ducts occurs, of course, only in early infancy. The peculiar form seen in India and syphilitic cirrhosis are also peculiar to infancy. Cirrhosis with enlargement is more common than cirrhosis with diminution in the size of the liver. All causes which produce the disease in adult life may also produce it in childhood. Additional causes in childhood are congenital obliteration of the bile-ducts and congenital syphilis, the latter being undoubtedly the most frequent cause. Alcohol is responsible for from 10 to 25 per cent. of the cases, its importance varying with the different authorities. Many cases go to show that very small amounts of alcohol, if taken regularly by children, may produce cirrhosis. In about 60 per cent. there is no evident cause. The author thinks it probable that the products of abnormal fermentation or decomposition in the digestive tract are a more frequent cause of cirrhosis in infancy than in adult life, and that it is also probable that the products of bacterial growth in the intestines or elsewhere are more harmful at this age. The cases which have apparently followed overfeeding are presumably due to this cause. On the subject of cirrhosis with congenital obstruction of the bile ducts, the writer says, the etiology is obscure. It is certainly not due to syphilis, but its early onset and the occurrence of several cases in the same family would suggest that the obstruction is due to arrest of development. He suggests the following as a plausible explanation: Irritant substances may pass through the placenta to the fœtus. They may then pass directly to the liver, or reach it indirectly after passing through the general circulation. The conditions necessary for the production of a mixed cirrhosis are then produced. The cholangitis then descends to the larger ducts. Stenosis and obliteration readily follow, because of the extremely small size of their lumen at this time. Additional points in favor of primary cirrhosis are: (1) The constant occurrence of cirrhosis in obstruction of the bile-ducts in infants, compared with its rarity after obstruction of the large ducts in adults. (2) The large size of the liver, which is usually small when due to obstruction in later life. (3) The enlargement of the spleen, which does not occur in uncomplicated biliary obstruction. All these facts make it reasonable to suppose that the disease is due to irritants derived from the mother, which cause a cirrhosis and cholangitis, the cholangitis descending and obliterating the larger ducts.

Journal of the American Medical Association, Sept. 13, 1902.

The Influence of Biliary Acids on Surface Tension.—C. D. Spivak notes the fact that a pinch of flowers of sulphur thrown on water or urine free from bile will float on the surface, but on the addition of one drop of bile to a quart of fluid the sulphur will at once sink to the bottom. This is known as Hay's test, and is based on the law of surface tension. It is due to the presence of bile acids; one part of either glycocholic or tamocholic acid in 120,000 parts of water lowers the surface tension, and the sulphur sinks. No other substance in the body, except soap, has the same reaction as the above. It has been found, however, that acetic acid, alcohol, ether, chloroform, essence of turpentine, benzoin and its derivatives, phenol and its derivatives, and analin also cause the sulphur to precipitate. All fluids with a surface tension greater than fifty dynes per centimeter do not allow sulphur to fall, and in all fluids with a tension less than fifty dynes the sulphur rapidly settles. Lycopodium bears the same relation to fluids with a tension of thirty dynes as flowers of sulphur to fluids with a tension of fifty dynes. Spivak finds the following facts to be true and require consideration in determining the applicability of the test and the conclusion to be drawn therefrom: (1) The specific gravity of the fluid has no influence on the accuracy of the tests. (2) The reaction of the fluid has no effect on the test. (3) In order to obtain correct results, the fluid must be clear. Cloudy or turbid urine must be filtered. (4) The urine must be free from bubbles. (5) Urine examined immediately after it is voided gives invariably the reaction for bile, because heat reduces surface tension. The urine must, therefore, be cooled off before the test is made. (6) In several cases where the reaction for bile pigment by Gmelin's test could not be obtained, the presence of bile acids could be demonstrated by the sulphur test. (7) In a case of syphilis of the liver, the urine gave the reaction for bile acids. (8) The urine for several patients in advanced stage of tuberculosis with swelling of the lower extremities, gave the reaction for bile acids. (9) The stomach contents of a patient removed on two consecutive mornings, and which consisted almost entirely of bile, did not give the sulphur reaction. (10) Urine of three cases of pregnancy in their sixth, eighth, and ninth months, respectively, gave the bile acid reaction; (11) After having experimented with more than one hundred and fifty different powders, Spivak has found that boracic acid, iodoform, acetanilid, salol, calomel, salicylate of bismuth and salicylic acid possess this property as does sulphur, only in a feebler degree.

Medical News, September 13, 1902.

Pathology of Empyema.—David Bovaird, Jr., emphasizes the following points in the pathology of empyema: (1) Its frequency in children. (2) The frequency of bilateral cases. (3) The impossibility of drawing sharp distinction between serofibrinous pleurisy and empyema. (4) The creamy consistency of the exudate in many cases. (5) The frequency of pneumonia, especially bronchopneumonia, as a preceding or accompanying lesion. (7) So far as concerns the bacteriology of empyema, the pneumococcus is present in the great majority of cases in children, especially in the thick creamy exudates. The streptococcus or staphylococcus pyogenes is found in a much smaller percentage of cases, especially in those not associated with pneumonia and characterized by thin purulent exudates. (8) Tuberculosis is present in but a small percentage (6 per cent.) of cases.

Surgical Treatment of Empyema; a Report Based on Seventy-five Cases, Observed Chiefly in St. Mary's Hospital for Children.—Charles N. Dowd gives the following summary of his paper: (1) For simple cases of empyema the following treatment is used: Excision of about one and a half inches of the seventh or eighth rib in the posterior axillary line; light ether anæsthesia is usually employed; the purulent coagula are removed; short rubber tubing, cut partly across, doubled and held by large safety pins, is used for drainage; abundant gauze dressing is applied and changed when saturated. (2) If the patient's condition contraindicates general anæsthesia an incision into the chest may be made between two ribs under cocaine anæsthesia. (3) Aspiration is only used to give temporary relief in patients who are in great distress from the pressure of the fluid, or temporarily to relieve the second side of a double empyema after the first side has been opened. (4) The patients are allowed out of bed as soon as is practicable, and the expansion of the lung is encouraged by forced expiration. (5) Irrigation is only used where there is a foul-smelling discharge from necrotic lung tissue. (6) Secondary operations are not done until good opportunity has been given for healing; usually three or four months should have elapsed after the primary operation, and there should have been no noticeable improvement for about a month. (7) In the secondary operation, the expansion of the lung should be encouraged by incising, stripping back, and, if necessary, removing portions of the thickened pulmonary pleura. (8) The examination of forty-four of the patients at long periods after operation indicates that recovery is usually complete in the simple cases, and that there is surprisingly little deformity in most of the severe cases.

A Case of Hepatic Abscess.—Emma W. Demaree reports this case of hepatic abscess, which developed in a puerperal woman. On the morning of the tenth day after confinement, the patient complained of pain in the right side and back, in the region of the liver, and of a general malaise. In the afternoon there was severe and lancinating pain with vomiting. The patient was most comfortable on the right side. There was marked tenderness in the region of the gall-bladder. There was no tumor. Some hours later there was a severe rigor, followed by a temperature of 105°, with profuse sweating. There was absolutely no trouble to be found with the uterus. Pain and tenderness were wholly confined to the region of the liver. After the first day pain was not a prominent symptom. The treatment was directed chiefly toward securing elimination and sustaining the patient. Exploratory puncture was not allowed. Three days after the onset the patient was much improved. During the previous night a considerable quantity of bloody pus had been passed by the bowel. She had also expectorated material of like appearance. Examination of the pus by microscope revealed what looked like microtome sections of liver in a state of cloudy swelling. After a large amount of this pus had been discharged, a black sand began to pass. Later, at two different times, in advance of the sand, stringy masses were evacuated. These were doubtless the remains of the pus sac, and the inflammatory exudate thrown out in connection with the rupture of the abscess into the colon. About three months after confinement the patient was able to do her work, and was free from the attacks of stomach trouble, of which she formerly complained. The writer asks the question: Did the biliary concretions, which seemed to be the exciting cause of the abscess, form in the gall-bladder and rupture into the liver or did they originate in the liver? As to the puerperal state, the writer thinks it may have had something to do with the pus formation, on account of lessened resistance of the tissues at this time, but the history of the case shows that it was not responsible for the entrance of the pus organisms.

New York Medical Journal, September 13, 1902.

The Diagnostic and Therapeutic Value of Ureteral Catheterization.—L. Gross reviews the history of this procedure, reporting one case in which a diagnosis of pyelitis of the right kidney was made. Irrigations into the pelvis of the organ and into the bladder with ten grams of a 1:1000 silver nitrate solution cured the case. The author's views as to the status of the method are thus expressed: *Diagnostic Value:* To determine (1) Whether the bladder or the kidney is the seat of the affection (2) The presence or absence of a kidney; (3) Which kidney is involved; (4) The site of the lesion; (5) The functional capacity of each kidney; (6) The presence of a calculus in the ureter or pelvis of the kidney and its exact location; (7) The presence of strictures in the ureter and their exact location; (8) The diagnosis and site of ureteral fistulæ; (9) The presence of a pyoureter; (10) A differential diagnosis between diseases of the kidney and the surrounding organs; (11) At times a tuberculosis of the kidney; (12) The diagnosis of pyelitis, pyelonephritis, pyonephrosis, hydronephosis, movable kidney, neoplasms of the kidney, or renal lithiasis; (13) Abnormal congenital conditions of the ureter. *Therapeutic Value:*—(1) To cure pyelitis and certain cases of pyonephrosis and hydronephrosis; (2) To drain pocket formations; (3) To dilate strictures of the ureters; (4) To dislodge small calculi of the ureter; (5) To drain the kidney after nephrotomy; (6) To prevent injury to, and stitching together of, the ureter in certain operations; (7) To prevent and cure renal fistulæ; (8) As a guide to certain operations on the pelvis of the kidney. Strict asepsis robs the method of any danger of infection.

A New Method of Staining the Malarial Parasites, with a Description of the Staining Reactions.—C. F. Craig uses the following solutions: Solution A.—A saturated aqueous solution of methyl violet B. This solution should be prepared with distilled water and should be at least three weeks old. Solution B.—A 5 per cent. solution of eosin. The method pursued in staining specimens is as follows: Very thin blood smears are made upon perfectly clean cover glasses. These smears are hardened in absolute alcohol for from five to ten minutes. They are next carefully dried and stained with solution A for ten seconds; then thoroughly washed in water and stained with solution B for from three to five seconds. The specimens are finally carefully dried and mounted in Canada balsam. As will be seen, the time for staining is very short, which is an improvement over the valuable methods which have heretofore been proposed. The following precautions are to be observed: (1) Both staining fluids should be prepared with the Grubler colors; (2) The methyl violet solution should be at least three weeks old. (3) The smears should be thin and the blood evenly distributed over the cover glass. In thick smears the coloring is very diffuse and the distinction between the corpuscles and parasites nearly obliterated. (4) The methyl violet solution should not be allowed to act longer than twenty seconds at the most, otherwise the staining is too intense. (5) The eosin solution should not be allowed to act for more than five seconds, for the same reason. (6) The specimens should be thoroughly dried before mounting, and thoroughly washed and dried between the applications of the stains. The stain colors the red cells a uniform dark blue, giving to the infected red cells a peculiar and destinctive color, enabling one to at once pick them out from the others. It differentiates protoplasm, nucleus, and chromatin.

American Medicine, September 13, 1902.

Cases of Carcinoma and Sarcoma Recently Treated by Electric Sterilization.—G. Betton Massey refers to a paper in which he reported a series of thirty-eight malignant tumors that had been placed under the cataphoric diffusion of electrolytic salts of mercury and zinc for destruction and sterilization, with the following results: In eight cases a cure was obtained; in twenty cases the local disease was removed, but the patient succumbed ultimately to metastases that were apparently existent at the time of the application; in eight cases the method, while still new, had failed to stay the progress of the local disease, and in two cases the patients died during the treatment A later review of these cases shows one patient, reported as cured with recurrent carcinoma of the breast and axilla, has died from metastatic growths in the mediastinum without return of the local disease. The remaining seven successful cases have stood the test of two more years without redevelopment of the disease. In addition to these, fifteen other cases have been treated. Of these, nine appear to be cured, two patients were temporarily helped without arrest of the disease, and four patients died shortly after the application was made. The widely differing character of these cases and the desperate nature of those terminating fatally gave, however, very little ground for a statistical inquiry, the chief value of this report, according to the author, lying in the study of the individual cases described.

Surgical Features of Typhoid Fever.—Thomas McCrae and James F. Mitchell sum up their two years' experience as follows: There have been treated 275 cases. Of these a certain number had unimportant complications, as boils or abscesses, the cultures from which, in every instance, yielded pyogenic cocci. Periostitis and perichondritis have been seen occasionally, always subsiding without surgical interference. Glandular affections, especially mastitis, occurred, but were not serious. Abscess of the liver occurred once, with recovery, the cultures being practically negative. There have been symptoms of cholecystitis in five cases, of which three subsided without operation, one patient was operated upon and recovered, while in one the gall-bladder ruptured and general peritonitis resulting in death followed. Appendicitis was suspected on admission in three cases and developed once during the course of typhoid fever. Perforation of the intestine occurred in eight patients. Of these seven were operated upon with two recoveries, a third dying of toxæmia after a week. All of these seven were recognized within nine hours, except two, in which hemorrhage from the bowel accompanied the perforation. In one case operation was not advised, because the patient was evidently in extremis. Exploratory laparotomy was done in two cases, in which no perforation was found. In one the symptoms proved to be due to intestinal hemorrhage; in the other to a low grade of peritonitis. The first patient died, the second recovered. Eleven patients with suspicious abdominal symptoms were not operated upon. Of these, two died and the autopsies showed no perforation. The remaining nine recovered.

Philadelphia Medical Journal, September 13, 1902.

Note of a Case in Which the Time Required by an Inappropriate Food to Produce Scorbutic Symptoms Was Accurately Noted.—J. D. Milton Miller reports the case of a child first seen at three and a half months who developed scorbutic symptoms exactly eight weeks after the commencement of condensed milk in the dietary. The child was undersized, and its digestion was not capable of assimilating the amount of proteids suitable for its age. A deficiency of proteids—in other words, a too dilute food—is often an influential factor in the production of this disease. Its food had been changed from time to time, and at twelve months it weighed seventeen and three-quarter pounds Before the attack of indigestion which preceded the use of condensed milk, the child, who was at that time eleven and a half months old was getting 2 per cent. of proteids. It was, besides, fairly well, although it was underweight. So it is more than probable that the scurvy was the direct result of the condensed milk. For a week after the condensed milk was first given the child was fretful and had no appetite, and this period was followed by the appearance of genuine scorbutic symptoms. The condensed milk was at once stopped, and a diet of fresh cow's milk and barley water was given, with fresh beef juice and the juice of half an orange daily. The child completely recovered within a week.

A Case of Puerperal Neuritis.—Charles J. Aldrich states that paralysis complicating and following the puerperal period is sufficiently rare to merit a detailed report of all cases. The case reported is that of a woman aged twenty-seven years. She has had three children, the youngest ten months. She never had a miscarriage. During the latter months of her last pregnancy, she suffered much pain in her legs, which felt powerless and heavy. Her arms were strong. Examination showed her heart, lungs, and abdominal and pelvic organs to be normal. There was no ocular affection, nor any weakness or paralysis of any muscles or group of muscles in the face or upper extremities. The walk is ataxic—distinctly so—and a marked foot drop is present on the right side. She cannot stand with her eyes closed. She stands poorly even with them open, when the heels and toes are placed together. Both knee-jerks are absent, as well as front tap and Achilles jerk, and plantar reflexes. There is a well-defined anæsthesia of the sole of the right foot and toes. There is a distinct atrophy of the intrinsic muscles of the feet, most marked in the right. There is also some atrophy of the anterior tibial and peroneal groups, most marked on the right side. Tendon reflexes in the upper extremities are quite indistinct. The tongue is protruded straight. The right labio-nasal fold is deepest. The left pupil is the larger. Both react promptly to light and accommodation. The palpebral openings are equal. The disks and fields are normal. A fine lateral nystagmus is present. The sense of position is not good. The diagnosis of puerperal neuritis, paraplegic in distribution and ataxic in type, seems fully warranted.

How to Recognize Tuberculous Changes in the Apices of the Lungs on Percussion.—Henry E. Stadlinger believes that the method which he describes will lead to an earlier diagnosis than the ordinary method of percussion by comparison. The first step is to find the amount of respiratory mobility of the lungs at their posterior bases. Both expiration and full inspiration are marked with a pencil. This will show if the lungs functionate well. At the apices the lung tissue is mapped out from the surrounding tissues. The patient should stand as near the center of the room as possible The percussion of the two apices is compared If there is a difference in pitch, there will be a difference in the width of the apex resonance area. It is then needless to go further. But if there is no difference, then the apex is mapped out from the surrounding tissues: first the inner border line is found, and continued to the sternoclavicular articulation. The posterior border line is also found. Then, from the supraclavicular space, the outer border line is found, and marked. This outer line is curved with the convexity pointing toward the median line, and, crossing the clavicle about its outer one-third it disappears in the axilla. This line is followed posteriorly to the suprascapular region. The border line is difficult to obtain at this point. After both sides are mapped out, they are compared by measuring them with an ordinary tape, from a point at the acrimoclavicular articulation to where the inner border line crosses over the shoulder. Then a measure is taken from the same point to the outer border line, and this distance is subtracted from the first distance found, and the result is the width of the apex resonance. In cases of deformity of the chest one or other apex may show the border line higher or lower, but if the width of the apex resonance is the same, this is of no importance. But if one of the sides is narrowed, the case is different. The exact figure of the normal width cannot be given, but it is approximately about 4½ to 5 cm. Respiratory mobility at the apices should always be noted. The stethoscope should always be used.

The Lancet, September 6, 1902.

The Clinical Use of the Ipecacuanha Alkaloids.—R. B. Wild extols the virtues of emetine, of which he uses two salts, the hydrochloride and hydrobromide. Solutions of these in 20 per cent. alcohol remain clear indefinitely. The hydrobromide in such solution, one grain to the ounce, is very active and reliable, the adult dose being from 5 to 20 minims as an expectorant and depressant and from 1 to 3 drams as an emetic. The emetine is superior to cephæline, to the third alkaloid in ipecac root and to ipecacuanhic acid.

Note on the Origin of Urine Albumin.—The experiments of Ludwig Aschoff support the view that the albumin present in nephritic urine is derived from the blood and is different from the specific kidney albumins. According to the results hitherto attained, there appears to be a difference between the blood serum albumin and the kidney epithelium albumin. But other experiments point to the existence of a relationship between the proteid constituents of the different epithelial cells as well as of the blood cells, inasmuch as the injection of one kind of cell may yield a serum which acts on several species of cells.

A Plea for Tenotomy of the Tendo Achillis in Complicated Fractures of the Lower Extremity.—W. T. Thomas calls attention to the fact that, while the great majority of fractures of the lower extremity are readily adjusted and call for no special remark, certain fractures are always troublesome and difficult to treat, *e. g.* (1) Fracture through the lower end of the femur; (2) Olique fractures of the tibia; (3) Fracture of the tibia and fibula low down; and (4) Fractures of the os calcis. When the chief deforming agent is the gastrocnemius, its action must be prevented, and in slight deformities this is readily brought about by flexion. Traction often increases the trouble or proves irksome after a few days, even if it does not damage the skin. When the muscle is acting at a great mechanical advantage, the hope that it may be overcome by steady slowly-increasing traction is often doomed to disappointment. By traction on the leg in a very oblique fracture of the tibia the deformity is often increased, and the attempt to remedy matters by pads often makes matters worse, for although the pointed fragment under the skin in front may be depressed, the sharp end of the other fragment may be, and often is, pushed backward into the calf muscle, and the subsequent result is not satisfactory. Slight degrees of flexion at the knee can be tolerated, but extreme degrees cannot. If, then, it is found that a position compatible with comfort does not relax the gastrocnemius, the tendo Achillis ought to be divided.

Environment as a Cause of Ague.—M. D. O'Connell presents the following summary of his views: (1) Cases of fever, clinically identical with malaria, occur in the blood of which parasites could not be found after repeated search before quinine had been given. (2) The meteorological environment found where such cases occur, and indeed in all malarial climates, increases the amount of water in the blood of those exposed to its influence by impeding elimination through the skin and lungs (evaporation—heat loss) and through the kidneys. (3) There is known to be increase of water in the blood of those suffering from ague (Liebermeister). (4) Increase of water in the blood increases metabolism, *i. e.* heat production, and produces a rise of body temperature (Payne). (5) As environment thus causes diminished heat loss from the body and increased heat production within the body, it is plain that it causes pyrexia. (6) This pyrexia must be of intermittent variety, as the environment which produces it is of intermittent intensity, *i. e.* undergoes diurnal variation. (7) Elimination of water from the blood (sweat) in ague reduces the temperature to normal. (8) Increase of water in the blood produces poikilocytosis, pseudo-parasites, liberation of hæmoglobin, extensive destruction of red blood corpuscles, and melanæmia. (9) An extreme degree of these changes obviously leads to hæmoglobinuria. (10) Increase of water in the blood produces enlargement of the spleen. (11) Removal from the environment that produces increase of water in the blood usually cures ague. (12) All treatment of ague which is efficacious reduces the amount of water in the blood. (13) From these facts O'Connell thinks it is not unreasonable to conclude that those cases of ague or intermittent fever in which no parasites can be found are demonstrably due to the environment under which they arise.

British Medical Journal, September 6, 1902.

Buttermilk as an Infant Food.—Adolph Baginsky concludes that buttermilk, as prepared and recommended by the Dutch physicians, is a good food for acutely and chronically sick infants. Prepared buttermilk is well borne soon after attacks of acute dyspepsia and summer diarrhœa. In chronic diarrhœa and chronic enteritis cases it may be looked upon as a life-saving preparation. It is to be hoped that more observations be made upon its use as an actual food for healthy infants. In the cases which the author has observed for a long time, he has never seen disturbances of nutrition, such as rachitis or scorbutus, develop.

A Phenomenon of Exophthalmic Goiter.—Howard B. Gladstone describes this phenomenon, which is a striking demonstration of the purely vascular nature of the enlargement of the thyroid in exophthalmic goiter. The patient lies on his back in bed with all pillows removed, and then raises his head off the bed and looks toward his feet. He does this with no assistance, using only the muscles of the neck and back. The cervical fascia is put on the stretch, and the tension empties the engorged vessels of the gland on which the enlargement depends in this disease. In this bloodless state, the goiter may be compared to the state in which it is usually found post mortem, where after cessation of the heart's action, its dimensions are much reduced, its vessels not being full. The writer thinks that knowledge of this phenomenon may be useful as an aid to diagnosis in swellings of the thyroid.

A Case of Oyster Poisoning Simulating Smallpox.—Charles Fraser reports the history of a patient aged thirty-three. He had six small distinct vaccination marks, three on each arm. On admission to the hospital, the patient's condition was one of extreme exhaustion. He complained of headache, pain between the shoulders, giddiness, and great weakness. The temperature was 101°F. The mental condition was clear, although the expression was listless The pulse was quick, small, and of low tension. The respirations were rapid. On the forehead was a profuse papular eruption, with a good deal of merging of the individual papules, and hyperæmia of the surrounding skin. The mucous membranes were clear, and the conjunctiva somewhat injected. On the chest, abdomen, and extremities, was a rash of a different type. It consisted of small, round, discrete. slightly raised spots, fading on pressure, and with no feeling of shottiness. Four days previous to his entrance at the hospital the patient had eaten oysters. This was followed the next day by diarrhœa and sickness, and on the second day after this, the rash appeared. The history of an illness of four days' duration, with the appearance of the rash, on the third day, the very characteristic eruption on the face, the great debility and the hurried respiration, with normal lungs, appeared to the author to point to the diagnosis of smallpox. The absence of backache, the temperature of 101° F. with rash developed, and the history of oyster eating five days previously were disconcerting facts. Aside from these facts, however, the evidence seemed to be in favor of smallpox. Two days after his entrance to the hospital, the eruption had entirely vanished. His temperature was normal, and he felt quite well.

Defective Coordination, in Utero, a Probable Factor in the Causation of Certain Congenital Malformations.—John Thomson states that there are at least three types of congenital malformation of hollow viscera in which the main anatomical abnormality present consists in very great muscular hypertrophy, for which no permanent organic cause is discoverable. These are: (1) Congenital hypertrophy of the bladder with dilatation of the ureters and renal pelves, and with no organic obstruction Although in most cases of congenital hydronephrosis there are organic constrictions which account for the condition, still there are a considerable number of cases in which there has been no permanent cause of blocking whatsoever. (2) Congenital hypertrophy of the colon with no organic stricture. In many cases of constipation with dilatation and hypertrophy of the colon dating from early life, there has been no trace of narrowing. (3) Congenital hypertrophy of the pylorus and stomach wall. There are several points common to all of these three morbid conditions. In all, the main abnormality consists in enormous hypertrophy of the muscular coat of a hollow organ which is known to be functionally active to some extent in utero. The amount of the hypertrophy found in cases dying soon after birth is so great that it is generally admitted that it must have been present, at least to a considerable degree, during intrauterine life. In none is there any evidence of such permanent organic obstruction as we should expect to find giving rise to the overgrowths of muscle. No other abnormalities are usually present, except such as may reasonably be regarded as secondary to the muscular hypertrophy. As to the pathology and etiology, the causation of the muscular hypertrophy is the most important point to be settled. The two chief hypotheses concerning it are: First, that it is a primary developmental hyperplasia; a sort of localized gigantism. Although there seems no impossibility in the idea of a local gigantism of the pylorus or bowel, or bladder, the author doubts very much whether there exists a single instance of a localized true hypertrophy of muscle being primary in character. The second hypothesis is, that it is a secondary hypertrophy resulting from overexertion. We may expect that hypertrophy may occur in utero under the same conditions in which it does after birth. For the proper working of all hollow organs, perfect harmony of coordination is necessary, and even slight disturbance of the coordination may lead to greatly exaggerated exertion. It is most difficult to decide upon the nature of this derangement. The writer concludes his paper with a discussion of congenital hypertrophy of the pylorus. He says that the comparatively isolated character of this malformation tells against its being really a teratological condition. The prominence of the spasmodic element in the symptoms after birth suggests the possibility of a similar spasm in utero. The apparent continued growth in size of the pylorus after birth, while the symptoms last, suggests the probability of a similar growth in fetal life. The gradual disappearance of the symptoms in some cases, while there is reason to believe that the anatomical condition remains unchanged, and the immediate improvement after stretching of the pylorus in others, which are, under the circumstances, points in favor of a functional causation. They also suggest that the disturbance is of a transitory nature. In one case in which the pylorus was stretched, the child improved at once, and has remained well for three years. This seems a further indication of the transitory nature of the case.

Münchener medicinische Wochenschrift, August 19, 1902.

Treatment of Phthisis by Subcutaneous Injections of Arsenic.—H. Cybulski uses for this purpose a mixture composed of natr. arsenicici .2, sol. of ac. carbolic (½ per cent.) 20. For the initial injections the Provaz syringe is only partially filled. The dose is increased .1 every day or every second day until an entire syringe full is injected at one time. In all cases the injections were given daily for a period of twenty days. Of ten patients treated by this method four showed improvement. This improvement consisted in a reduction of the fever and night sweats and an increase in the appetite, bodily weight, and general strength. No effect was produced upon the intestine or heart Albumin never appeared in the urine, and hence the kidneys were not irritated by the injections. The lung lesions did not appear to be in any way influenced by the treatment.

Diagnosis of the Inherited Phthisical Disposition.—Georg Sticker says that an inherited predisposition to phthisis may be suspected in all those persons who show a reduction of inspiratory power or, more properly speaking, when the ability for inspiration is reduced out of proportion to the general muscular power of the individual. For measuring the inspiratory power the author has devised an instrument known as the thoracodynamometer, upon which the result obtained in any individual case is recorded in kilograms. The normal inspiratory power measured upon this instrument corresponds to from 32 to 46 kg. For estimating the general muscular power the hand dynamometer is used. Normally, the maximum pressure exerted by the right hand records upon this instrument from 25 to 44 kg. By the combined use of these instruments therefore the relation of the inspiratory to the general muscular power may be estimated, and an hereditary predisposition to phthisis affirmed or negatived.

Duration of the Results Obtained by the Sanatorium Treatment of Phthisis.—F. Reiche submits the following figures as coming from the sanatorium at Hansestadte; up to the end of 1901 1773 persons had submitted themselves to at least four weeks' treatment in this sanatorium. Of these, upon discharge, 1364 were able to return to their ordinary avocations; 312 were only partially able to do so; sixty-six were totally incapacitated from any further work; one died in the institution. These figures include all patients who were received from 1895 to 1900 inclusive If we take the cases as they were discharged by years during this period and estimate the proportion who at the end of 1901 were capable of persuing their ordinary avocations, we obtain the following figures: 1895, 52.7 per cent.; 1896, 65 per cent.; 1897, 67 7 per cent.; 1898, 58 1 per cent.; 1899, 61.7 per cent.; 1900, 62.4 per cent. The following had died to 1901 (the year relates to the date of their discharge): 1895, 27.3 per cent.; 1896, 17.1 per cent.; 1897, 14.2 per cent.; 1898, 18.3 per cent.; 1899, 11.6 per cent.; 1900, 4.8 per cent. While these figures are encouraging, they nevertheless show that the sanatorium treatment of tuberculosis is only of indirect value in the conflict against this disease, and that other ways and means must be brought into play before the final victory can be obtained

Munchener medicinische Wochenschrift, August 26, 1902.

Inflation of Air Pillows and Cushions.—Landgraf advises that all air pillows and cushions be provided with valves similar to those used in bicycle tires. They can then be inflated by the means of an ordinary bicycle pump, and the disgusting method of inflating them with the mouth, which is now in almost universal use, will be eradicated.

Early Diagnosis of Hereditary Subluxation of the Hip-Joint.—Peter Bade says that a determination of the position of the adductor folds of the thighs is of great value in the early diagnosis of this condition. If a normal child is placed upon its back and the legs extended and closely approximated it will be seen that the inner and lower extremities of the adductor folds exactly meet. If, however, there is a subluxation the inner and lower extremity of the fold on the affected side will fall below the similar extremity of the sound side. The author has used this sign as a means of diagnosis for some years, and has found it to give the greatest satisfaction. One case is reported in detail.

The Influence of Chronic Pulmonary Tuberculosis upon the Nerves and Senses.—H. Engel emphasizes the influence of tubercular processes upon the nerves and senses, and the frequency of the so-called neurasthenic tuberculosis. It seems probable that the neurasthenic appearances are brought about primarily by the action of the tuberculous toxin upon the nerve centers, although in many instances this action undoubtedly extends to the entire nervous system. The treatment of neurasthenic tuberculous patients demands the greatest care. In most instances they must be treated essentially as neurasthenics, and brought within the close personal control of the medical attendant. In such patients the administration of stimulants and narcotics must be carried on with the greatest caution. Neurasthenic stomach disturbances often give rise to the greatest apprehension, since they, as a rule, markedly interfere with the general nutrition. Usually such disturbances are the most successfully treated by lavage.

Berliner klinische Wochenschrift, August 18, 1902,

Extensive Pyometra in a Uterus Bicornis Puerperalis.—Emil Senger's patient had passed through a normal pregnancy and labor. The puerperium was likewise normal up to the twenty-second day, when the patient developed a temperature which was irregular but continuous. This condition continued for about two weeks, when Senger was called to see the patient. An examination showed the presence of a large tumor to the left of the uterus and in evident connection with the same A diagnosis of parametritis with circumscribed peritonitis was made, and an immediate operation advised. Previous to operating, an exploratory puncture showed that the tumor contained a thick purulent fluid. Upon opening the abdomen it was found that a true uterus bicornis was present. The right uterus was the one in which the pregnancy had taken place. The left uterus was the seat of the trouble. This had been occupied by a portion of the decidua, etc., which had not been expelled. Infection had in some manner taken place, and had given rise to an extensive pyometra in this uterus. The contents of this uterus were evacuated, and the whole thoroughly cleansed. It was not amputated on account of the bad condition of the patient, the pulse suddenly becoming very high and the respirations rapid and shallow Following the operation the fever subsided, and the general condition of the patient improved greatly Seven days after the operation the tempertaure again became elevated. For this reason the abdomen was reopened and the left uterus amputated Recovery followed in due time.

Berliner klinische Wochenschrift, August 25, 1902

Differentiation of the Typhoid, Colon, and Dysentery Bacilli.—Martin Klopstock has combined the two media recommended by Barsiekow in an endeavor to evolve a medium which would give a satisfactory differentiation between typhoid colon and dysentery bacilli. For the combined media, 1 per cent of lactose is added to the nutrose-NaCl. solution, which contains 1 per cent of glucose. In this medium, after twenty-four hours' incubation, the dysentery bacillus produces acid, but no coagulation; the typhoid bacillus produces acid, clouding, but no coagulation; the colon bacillus produces acid and complete coagulation.

Deutsche Medicinische Wochenschrift, August 21, 1902

Simultaneous Appearance of Erysipelas and Scarlet Fever in the Same Person.—P. Haller reports the case of a patient who developed facial erysipelas. Upon the morning following the evening on which the diagnosis was made an abundant scarlet rash appeared upon the chest and arms. This rash spread rapidly, and was soon accompanied by the characteristic tongue and throat appearances of scarlet fever. The scarlet fever ran a normal course and terminated in recovery. Streptococci were cultivated from the facial erysipelatous lesions. It is firmly established that erysipelas is due to a streptococcus infection. The simultaneous appearance, therefore, of this disease and scarlet fever in the same person would seem to show that the latter disease is not of streptococcus origin, since it can hardly be supposed that the same microorganism could give rise to two separate diseases at the same time in the same individual.

French and Italian Journals

Cases of False Metritis of the Menopause.—A. Doléris presents an instructive paper on the diverse troubles which are incident to the "critical period." Certain authors have described a pathological entity under the name of metritis of the menopause. At this period there is often amenorrhœa for several months, followed by prolonged hemorrhage for some days. During this time the uterus is enormous, succulent, and very soft. It bleeds easily, and is subject to various malpositions. There is almost always leucorrhœa. The cervix is enlarged and turgid. The muscle is also affected, and there occurs a veritable pseudohypertrophy. The lesions are rather those of pseudohypertrophic atony, preceding atrophy. The muscle fibers have not the solidity and strength to maintain the muscle tonus. There is also senile degeneration of the vessel walls. The physiological troubles of the menopause are local and genreal; the local troubles consist of the uterine changes; the general troubles of general reflex troubles. The treatment of these troubles is very diverse. Hydrotherapy, in the form of cold douches, astringent injections, and antiseptic injections are made use of. Faradization gives good service. An alkaline régime is prescribed, and for arthritics, a vegetable and milk diet. Iodide of potassium is sometimes ordered. Application of oxide of zinc is used to combat eczema of the vulva. And finally hygienic measures, as life in the open air, are most valuable.—*La Médecine Moderne*, August 27, 1902.

Mental Torticollis.—E. Feindel says that mental torticollis is a tic of the neck. It is sometimes an intermittent gesture of rotation of the head, and then again it is an attitude of torticollis, which is prolonged for a longer or shorter time. It is, in fact, like every other tic, a psychomotor trouble, made up of two inseparable elements: a mental trouble and a motor trouble, the one being subordinate to the other. The predominating mental trouble is a weakness of will. This condition resembles that found in childhood; there is, to a certain extent, in spite of the progress of years, an infantile mental state The arrest of psychical development is often only partial and unequal. The unbalanced condition of certain of these patients is especially marked. These patients may, besides, present fixed ideas, obsessions, and impulsions. The motor trouble is the movement of rotation of the head. In the beginning it is a co-ordinated act, but by repetition it becomes habitual and automatic. Then, when its provoking cause has disappeared, the torticollis continues without any cause. If the excessive muscular contractions cease, there is nothing left of the torticollis. It leaves no traces of its existence, only to reappear a short time later. Sometimes the patient can correct the torticollis by an antagonistic gesture. The muscular contraction may be clonic or tonic. The movements may vary; there is the simple turning of the head to one side, and the inclination of the head to one shoulder, and the elevation of one shoulder, and so on through all the category. Mental torticollis is a chronic malady, without any tendency to spontaneous recovery. The prognosis is much better if the patient is treated early in the disease. It may then sometimes be cured. Although there are many methods of treatment, the most highly recommended is that of Brissaud—motor re-education. In severe cases it is well to order rest in bed and isolation before treatment is begun.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, August 28, 1902.

Fibroma of the Uterus in a Child of Thirteen Years.—M. P. de Cavaillon has communicated this interesting observation. The history of this patient, both personal and family, was negative. At the age of twelve years she first menstruated—a normal sign of puberty. The flow was striking only by its abundance. During eight months this child, at nearly regular periods, was afflicted by marked menorrhagia. When seen in December, 1901, the patient was in a state of extreme anæmia—pale mucosa and skin, maleolar œdema, digestive troubles, and palpitations, etc. Examination revealed a large mass of the size of two fists, occupying the pelvis, freely movable with the uterus. There was no affection of the sphincters. The pains extended to the perineum, and were especially felt during the period of flow. Intervention was proposed, but was not possible at the time. Later the menorrhagia was arrested for three months, but the pains increased. A new examination showed that the tumor had grown in size. The diagnosis of large uterus was made, but the difficulty was to tell the nature of the hypertrophy. The idea of menstrual retention had to be eliminated. Pregnancy was suggested, but that hardly seemed possible on account of the age and the social position. Operation was finally undertaken. Laparotomy revealed an enormous uterus, the surface of which was furrowed with enlarged veins. Puncture of the uterine cavity revealed nothing, and hysterectomy was performed. The wound was sutured in three layers, and a drain was inserted in the lower part. The tumor was very large, and weighed three kilograms. It was entirely concerned with the wall of the body of the uterus, and the cervix was not implicated at all. The mucosa presented no macroscopical ulcerations. The operation was followed by recovery. The tumor had developed as if the patient had been an adult. Its evolution had been abdominal rather than pelvic, and this, perhaps, explained the absence of pressure symptoms. If the tumor had remained in the pelvis, the pelvic organs would then have suffered. This tumor, occurring at the early age of the patient, is very rare.—*Journal de Médecine de Paris*, August 24, 1902.

Phlebitis of the Ophthalmic Vein and of the Cavernous Sinus, Following a Dental Abscess.—N. Couderc reports this very interesting case. The patient was a man 32 years old, large and strong. He was not an excessive drinker. He had never been ill, with the exception of a succession of a series of dental abscesses which developed at the same time about carious molars in the lower maxilla on the left side. On the eighth of December, 1898, a new dental abscess appeared on the left side. This was accompanied by fever and very pronounced swelling of the gum. The urine contained no sugar or albumin. On December 11, the fluctuating point was lanced. This was followed by a flow of pus from the wound. Purulent expectoration continued all day. There was no amelioration of the local symptoms: on the contrary, the patient grew worse. The swelling increased and extended behind the angle of the jaw. On the morning of December 13 there was a violent chill, lasting an hour, and followed by profuse sweating. This was repeated that evening and three times the next day. The fever increased, and so did the swelling. The whole left side of the face was swollen, and the trouble extended down towards the neck. The fever continued and the chills recurred every day. The liver and spleen were enlarged. Abundance of fluid was administered, and purgatives as well. The patient was also bled. But it did no good. The tissues were hard. It was a difficult problem to know what to do. On December 17 a very grave new symptom appeared. It was exopthalmous of the left eye, which extended that evening to the right eye. Conjunctival chemosis developed at the same time. Vision was disturbed. The patient, who retained consciousness, complained of severe lancinating pains in all of the inflamed region. Another painful focus developed in front of the left ear. The skin was clammy, the mouth was dry, and the lips fuliginous. On December 18 a large opening was made at the level of the left masseter. The bone was reached, but not a drop of pus appeared. The bone was denuded at every point reached by the probe. It was a subacute necrosis, for it had been scarcely ten days since the beginning of the trouble. After the operation the patient fell into a semi-comatose state. The next day the patient's condition was pitiable. On December 20, he was able to reply with pain to questions. The face was enormous, the eyes protruded, but not a drop of pus came from the incision. The wound was dry. That evening he became delirious and toward morning he died. The infection had without doubt reached the branches of the facial vein, and from there had penetrated by the anastomotic vessels to the ophthalmic vein. This was shown by the exophthalmos and the chemosis, which are constant signs of phlebitis of the ophthalmic vein. From there it reached the cavernous sinus. This was indicated by the delirium, the agitation and the semi-comatose state. It is probable that there existed in the patient at the same time an infectious phlebitis and a diffuse subacute phlegmon, with mortification of the tissues.—*Journal des Praticiens*, August 30, 1902.

Treatment of Localized Pruritus by Faradization.—Bouveyron presents a communication on cutaneous faridization as a general method of treatment of localized pruritus. He concludes that cutaneous faradization (positive unipolar or bipolar) exercises a marked action over pruritus in the greater number of dermatoses, and that this influence on pruritus can ameliorate indirectly the greater part of those cutaneous affections of which the pruritus is an important factor in their production or aggravation. He recommends this method especially to those practitioners who have not at their disposal the apparatus for giving static electricity or the currents of high frequency.—*Lyon Médical*, August 31, 1902.

Primary Cancer Obliterating the Large Left Bronchus; Tuberculous Bronchopneumonia of the Corresponding Lung.—H. Barth reports this case. Primary cancer of the large bronchi is a very rare affection. This patient was a woman twenty-seven years old. She entered the hospital, complaining of cough and oppression. She was of wretched appearance, and suggested a tuberculous history. But this present illness was of only fifteen days' duration. It had begun with cough, malaise, and fever. This was followed by a chill. She was thought to have pleurisy. She then entered the hospital, and the case was diagnosed as one of grip, of thoracic type, complicated with a left-sided pleurisy. There was immobility and rigidity of the left thorax, with feeble respiration, and some pleural friction sounds. There were fine râles over all the lung area. There was mucous expectoration. An exploratory puncture was made, and serous fluid came out of the opening. The later symptoms, as they appeared, rendered the diagnosis of tuberculosis probable. Then a marked retraction of the left side was noted. The patient grew worse and died in less than two months after entering the hospital. Autopsy revealed a tumor three cm. from the bifurcation of the trachea, and almost completely obstructing the caliber of the left bronchus. Histological examination showed this tumor to be an epithelioma.—*Le Bulletin Médical*, September 3, 1902.

A Case of Plexiform Neuroma.—Among the tumors of the nerves there is one, says Clément Delfosse, which until the last fifty years has been completely unknown. It is plexiform neuroma. The case which was studied by the writer was that of a child. The left side seemed normal. The right side was considerably changed. The orbital region was very much increased in size, and, in fact, the whole face was swollen. The upper eyelid, especially, was enormously swollen by a sort of œdema. Its lower border was everted so that it showed the palpebral conjunctiva. The lower eyelid was also distorted, but was not much changed in size. The ear was pushed downward. The right side of the nose was strongly depressed. On palpation, the upper eyelid felt soft, and gave the sensation of a lipo-angioma. After pressing gently on the swelling, and reducing it, there was perceptible a series of sinuous cords, which were hard to the touch. These cords were about the size of the temporal artery in the adult. On careful palpation, they were noted to be of stony hardness, and felt through the skin like bone. They were not tender on pressure and the skin was not changed in appearance. The child had never been injured in this region. The cords were diagnosed as plexiform neuroma. For the orbital tumor, the hypothesis of reducible lipo-angioma was admitted. Operation was performed, and a part of the cords removed. Three days after this the child died quietly, as if it had fallen asleep. Autopsy showed that the organism of the child was in a degenerated condition, and thus it was explained why it had not the vitality to resist the shock of the operation.—*Journal des Sciences Médicales de Lille*, August 23, 1902.

Tuberculosis of the Omentum Cured by Simple Laparotomy; Seven Years Later, Tuberculous Contraction of the Small Intestine; Lateral Enteroanastomosis with a Button; Recovery.—Piollet reports a patient from Poncet's clinic The woman had been in the clinic some years before, and the diagnosis of cancer of the omentum had been made. She was then fifty-five years of age, with nothing interesting in the history. She had suffered from gastrointestinal symptoms, incident to physical privations. There had been alternating constipation and diarrhœa, and pain in the stomach and intestines more intense two or three hours after eating, sometimes followed by vomiting, without hæmatemesis or melæna; progressive anorexia with emaciation. The abdomen, slightly enlarged, was very sensitive to pressure, and palpation detected a tumor as large as two fists, in the lower part of the abdomen. Vaginal touch revealed a large mass, especially prominent in the left posterolateral cul-de-sac, pushing the uterus to the right, and appearing to be entirely independent of this organ. There was no functional genital symptom; the menses, which had been normal and regular, had ceased since the age of fifty, and from that time the patient had not suffered from metorrhagia, nor from leucorrhœa. The lungs were normal. Believing the trouble to be a dermoid cyst or a malignant tumor of the ovary, a sub-umbilical, median, laparotomy was performed. There was a large mass, adherent to the posterior surface of the pubis, at the left border of the uterus, and extending into the small pelvis. This mass was only degenerated omentum. There seemed to be nothing abnormal about the stomach or intestine. The wound was closed without ablation of the mass, which appeared to be impossible. For a few days the temperature was elevated, but soon she was able to leave the hospital improved. The abdominal colic completely disappeared; the vomiting ceased, and for three or four years the digestive functions were normal, excepting a slight diarrhœa for several days. About two years ago the vomiting again appeared. This grew more frequent. The patient began to grow thin and the vomiting became almost incessant, and was preceded by true intestinal colic, with borborygmi. This began chiefly in the right side of the abdomen. The vomited material was the food but little changed, reduced to pulp. Sometimes there was bile and sometimes there was none. The right part of the abdomen was a little hard, but there was no distinct tumor. Diagnosis of probable stenosis of the beginning of the small intestine was made, due possibly to one of several causes. Laparotomy was performed and the omentum was found to be perfectly healthy. The stenosis was discovered in the small intestine and lateral anastomosis was done by means of Jaboulay's button, without suture, and the wound was then closed. The patient, at the time of this report, was in excellent condition. The wound was almost healed, and the painful symptoms had ceased.—*Lyon Médical*, August 24, 1902.

The Journal of Tropical Medicine, *August* 15, 1902.

Climatic Buboes in Kusaie, Caroline Islands.—C. F. Rife reports thirty cases of this disease, fifteen of which were under his immediate supervision, in his school for boys. One of the pupils contracted it on board a ship, where a sailor had had a long attack, and the other boys took it later. All the cases in the school were below the knee: one boy also having two small ulcers on one hand. No one had enlarged glands, except with the first infection. Treatment of the ulcers was rather unsatisfactory. Nothing seemed able to abort them in their long course. Hot fomentations, plain and medicated, were tried without apparent success. After the period of suppuration was passed, the pain was much relieved by dusting the ulcers with calomel. The climate is very moist; in 1899 there were 256 inches of rainfall. Extremes of temperature are 75° and 90°F.

Beriberi at Diego Garcia.—J. Bolton describes an epidemic which, he concludes, seems to teach that the germ of the disease, vegetable or animal, may remain latent in the human body for months, until local conditions favorable to its development obtain. It then proliferates and gives rise to characteristic symptoms. The gang of laborers who imported the disease to Diégo were loathsome in their habits, and as the vessels which brought them were located together with a number of other passengers in the fore part of the "'tween deck," which is always ill-ventilated, damp, stuffy, and dark. So that, coming from one of the Comores Islands with probably the germs of beriberi latent in them, they found themselves on board under conditions favorable to the proliferation of the microbe, and landed at Diégo, with the disease in a mild form. They afterward communicated it to some of their neighbors, but with their departure the disease disappeared.

Revue de Chirurgie, *August* 10, 19

Ano-Rectal Actinomycosis.—Léon Thevenot reports a case in which the parasite penetrated into the bladder which it traversed without leaving any trace to become localized in the anorectal region. The author discusses the various forms of this disease Treatment should be both medical and surgical, the chief medical agent being the iodide of potassium, locally applied Should this fail free incisions should be made, or excisions of the affected foci, with curettage and application of the thermocautery The progress is, however, extremely grave, death being the usual termination, from prolonged suppuration and, perhaps, from a special form of intoxication.

Bloody Operation for Replacement of the Head of the Femur in Irreducible Luxation of the Hip.—G. Gayet concludes that this operation deserves to become the classic method for the treatment of old and irreducible luxations. It is not dangerous, and the results obtained are far superior to those from other methods: the functional restoration is almost ideal, a good technique is absolutely essential to success. An external incision on the trochanter is usually all that is necessary Pathological luxation following acute diseases are so similar to the traumatic that their treatment should be the same. On the other hand, in coxalgic luxation, the general systemic condition, the changes in the bones, and the danger of reawakening the process form contraindications to replacement, except in a few special cases.

Fractures of the Posterior Tarsal Bones.—Etienne Destot says that the examination of a number of radiographs taken after the occurrence of accidents to the foot, shows that there is a region of predilection for the lesions, *i. e.* the posterior tarsal. It is bounded above by a horizontal line 3 cms. above the malleoli, and by a vertical line passing in front of the tubercle of the scaphoid, and includes the lower end of the bones of the leg, the astragalus, the calcaneum, and the articular extremities of the scaphoid and cuboid. The author gives the reasons for the special susceptibility of this region. Of the fractures of the malleolus, the posterior type is the more frequent. Fractures of the astragalus occur on the head or the neck of the bone, or on the posterior apophysis. Fractures of the calcaneum occur by tearing or by crushing. The author urges a study of these lesions clinically and by means of radiographs, and an early diagnosis.

Revue de Médecine, *August* 10, 1902.

The Pathogenesis of Phlebitis.—M. Censier, discussing cases in which simple traumatism or shock appear to bear a causative relation to the phlebitis, suggests that in conditions such as the puerperal state, where there has been general shock, or where the traumatism has acted on a uterine or periuterine venous system already overburdened and dilated, where the dilatation and stasis have acted upon the vessels of the whole lower limb—that there is some complex association of causes, and that some new element, probably some blood infection, must be added to such causes as an arthritic diathesis, individual predisposition, and a subacute rheumatic condition.

The Psychic Element in Hysterical Hemianæsthesia.—M. Bernheim reports two cases which, added to other cases previously reported, he considers a proof that "sensitivo-sensorial" hemianæsthesia may be directly added to hemiplegia by pure psychic dynamism. It may be initiated by medical examinations, which quite unconsciously make suggestion; it may be grafted by autosuggestion upon a diminished sensibility due to organic causes, increased by psychism and transformed into complete anæsthesia; it may have a real organic origin from the influence of some neighboring lesion upon the intracerebral sensory tracts, but the functional trouble, which should be transitory, may survive the organic reality as a psychic image, retained by autosuggestion. This may occur in patients who are not in the least hysterical. Psychic anæsthesia is not always hysteria.

Pathological Forms of Emotional Blushing.—P. Hartenberg describes several cases, and says that a distinction must be made between cases of uncomplicated emotional blushing, and those in which the fear of blushing is added to the original trouble. The first is a well-defined and frequent phenomena, due to shyness or shame, not related to fear, and becoming sometimes so intense as to constitute a real social infirmity. This is the blushing disease, ereuthopathy. When fear is added, the two emotions influence and react upon each other, and the whole phenomena becomes more complicated—blushing creates the fear of blushing—the fear creates the blushing, and the vicious cycle is extremely difficult to treat. Sometimes the fear is intermittent and paroxysmal, coming only with the blush it is then ereuthophobia. Again it may be constantly in the patient's mind, without distraction or relief, as a sort of fixed idea. It is then a veritable obsession of blushing.

Society Reports.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

TWELFTH ANNUAL MEETING.

Held at the Hotel Kaaterskill, N. Y., Sept. 2, 3 and 4, 1902.

(Special Report to the MEDICAL RECORD.)

First Day.—Tuesday, September 2.

The meeting was called to order in the parlor of the Hotel Kaaterskill, Catskill Mountains, N. Y., by the President, Dr. Fred H. Morse of Melrose, Mass. At the opening executive session several new members were elected.

Report of Committee on Static Machines and Condensers.—Dr. WILLIAM JAMES MORTON of New York City presented this report. He said that he had been unable to do much work in this field, and trusted that another would be appointed in his place. One great obstacle to the work was the sharp rivalry between the various manufacturers of static machines and the difficulty experienced in determining what really was the best mechine. The subject was, however, assuming a new and greater importance because of the prominent position taken by the static mechine in connection with the *x*-ray. He believed that the future would bring forth a far better static machine than any yet known. He had been particularly interested in the machine recently described by Gaiffe of Paris, a machine adapted for the production of the *x*-ray. There was certainly a difference between the static machine required for ordinary therapeutic use and that for the production of the *x*-ray. The former was best represented by the Holtz type. The spark was continuous and was well borne by the patient. The spark from machines of the purely Wimshurst type was, on the contrary, very painful, although this machine was extremely valuable for *x*-ray work. The direction for the improvement in static machines seemed to be with regard to the regulation of speed. If the speed could be carried up to one thousand revolutions per minute instead of two or three hundred, then smaller wheels could be employed, and the bulk of the machine could be reduced without diminishing the output. This would be a great desideratum for the *x*-ray worker.

Dr. G. BETTON MASSEY of Philadelphia remarked that all of the high-speed machines with which he was acquainted were very objectionable because of the loud humming noise they emitted. As to reducing the bulk, it should not be forgotten that a certain amount of space was required to insure proper insulation.

Dr. WILLIAM B. SNOW of New York City thought it unwise to insist so strongly upon the need of two separate machines, one for therapeutics and the other for *x*-ray work. If the *x*-ray machine were too heavy for ordinary electrical treatment, some of the plates should be thrown out of action; moreover excellent *x*-ray work had been done with therapeutic static machines.

Dr. J. D. GIBSON of Birmingham, Ala., said that it could not be denied that treatment with the Toepler-Holtz machine was decidedly more painful than with the spark from the Holtz machine, though the former was better for *x*-ray work.

The Action and Uses of the X-Rays in Therapeutics.—Dr. WILLIAM B. SNOW of New York City read this paper. The author expressed the opinion that the best apparatus for *x*-ray work was the static machine, consisting of ten plates, having a diameter of from thirty to thirty-four inches. In the past a low vacuum tube had been generally recommended, but it had been recently learned that their application was more limited than that of the high-vacuum tube. The *x*-rays were characterized by marked chemical effects. Upon living tissues they produce (1) diminished nutrition; (2) inflammation, and (3) deep necrosis. The extent of the inflammatory process depended somewhat upon the character of the ray, but more especially upon the length of the exposures and the idiosyncrasy of the patient. After a series of prolonged exposures if dermatitis were not produced, pigmentation of the part would occur. He was of the opinion that long exposures destroyed abnormal tissue elements of low vitality, but did not unfavorably affect normal tissues unless the exposures were too prolonged. When tumors of considerable size were treated in this way the reaction was apt to be quite marked, not only locally but constitutionally. It was probably the result of the breaking down of devitalized tissue with resulting auto-infection. Lupus and epithelioma of the skin were invariably cured by the *x*-ray, particularly by the brush discharge from a wooden electrode. It was suggested that a new and promising field was opened by combining operation with *x*-ray treatment in cases of cancer. He was of the opinion that no malignant tumor at the present time should be operated upon unless the affected part were subsequently subjected to treatment with the *x*-ray. The best method consisted in the use of the *x*-ray on alternate days. The author believes that laryngeal cancer can be successfully treated by the application of the *x*-rays from a high tube to the exterior of the larynx. His experience indicated that patients did not become more tolerant after a prolonged course of treatment, and that malignant tumors beneath the skin would disappear when subjected to *x*-ray treatment for a long time.

Dr. C. R. DICKSON of Toronto said that he had known the *x*-ray treatment, especially in cases of internal cancer, to produce diarrhœa in a number of instances. It was sometimes quite severe two or three days after the *x*-ray treatment, or just when the tissue was breaking down. As to the action of the *x*-ray, his idea was that the cells of the body, no longer under the control of the trophic nerves, break down much more readily than the normal cells under the action of the *x*-ray. He thought the brush discharge should be used in all *open* cases. When it was possible to "tan" the tissues the patient would be found much more tolerant to the *x*-ray.

Dr. ROBERT REYBURN of Washington, D. C., said that when the Ruhmkorff coil was used for the production of the *x*-ray it was necessary to employ a powerful battery, and the resulting excessive amperage seemed to him to explain the greater liability to produce *x*-ray dermatitis with coils as compared with the static machine.

Dr. J. D. GIBSON said that he had succeeded in causing a number of burns in cases treated by him with the coil. He believed that all chronic inflammations, whether within cavities or elsewhere, could be favorably influenced by the *x*-Ray, and that this new therapeutic agent would prove useful in cases of fibroids showing a tendency to hemorrhage.

Dr. M. F. WHEATLAND of Newport reported a case of chronic appendicitis, occurring in an elderly gentleman, which had been greatly relieved by *x*-ray treatment.

Dr. FRANCIS B. BISHOP of Washington, D. C., said that he had observed remarkably good results from *x*-ray treatment in tuberculous nodes of the neck, and the method possessed the very great advantage of curing with the minimum of scarring. Mention was made of a case of fibroid goiter that he was satisfactorily treating with the brush discharge.

Dr. R. J. NUNN of Savannah declared that *x*-ray burns and constitutional disturbance could be, for the most part, avoided by prudent treatment. One speaker had referred to the production of diarrhœa, and he had himself observed constipation following this treatment. He had seen *x*-ray burns produced as frequently by the static machine as by the coil.

Dr. WILLIAM JAMES MORTON deplored the tendency to obscure results by combining the brush discharge and other methods with the use of the *x*-ray. With an *x*-ray of given intensity he could not see any reason for expecting different effects from the use of the coil and the static machine, though the coil was harder on the vacuum tube. The action of the *x*-ray should be sufficiently intense to reach the part it was desired to treat, and this fact alone forced the scientific physician to employ high vacuum tubes in many cases. As physicists could throw very little light on the true nature of the *x*-ray, and pathologists were far from agreeing upon the nature of cancer, physicians must, for the present at least, depend wholly on clinical observation. The superficial cancers, particularly of the face, could be almost invariably cured without knife, caustic paste, or mercurial cataphoresis, simply by *x*-ray treatment. The other methods removed tissue in bulk, the quantity being determined by the judgment of the operator; the *x*-ray, on the other hand, possessed the power of influencing diseased tissue wherever found. He believed the *x*-ray screen should not, as a rule, be employed, for our aim should be to treat the parts widely. To that end, in the *x*-ray treatment of a tumor of the axilla, for example, he would also treat the entire thorax, both anteriorly and posteriorly. It was also important to keep the tube moving from one area to another. The great trouble in the *x*-ray treatment of carcinoma situated deeply in the abdomen was that such growths do not remain local for any length of time. He had never seen a case of cancer treated with the *x*-ray that had not shown more or less retrogression. He was of the opinion that some of the more limited cases of cancer should be treated by the *x*-ray until only a small nucleus was left, and then the surgeon should complete the cure by a minor operation. In this connection he desired to say that a prominent surgeon, only a few days ago, had written to him, stating that he was an absolute pessimist regarding the curability of carcinoma of the breast by operation, and adding that he only operated with that object in view out of deference to current opinion.

Dr. Snow, in closing the discussion, said that he believed that while it made no difference, as regards the therapeutic effect, whether the *x*-ray were obtained from the use of coil or static machine, provided the vacuum tubes were properly energized, experience had taught him that with the coil he would use up six tubes as against one with the static machine. He had advocated the brush discharge because in certain cases in which the *x*-ray had not been successful improvement had followed combining that treatment with the use of the brush discharge. He favored the use of the brush discharge in all superficial cases.

The Treatment of Cancer by X-Rays.—Dr. Clarence Edward Skinner of New Haven read this paper, which was based on an experience in thirty-three cases. There was complete disappearance of the growth in two cases, permanent reduction in fourteen and permanent arrest in two cases. There was no effect demonstrable on the size of the lesions in fourteen. The general condition of the patient was permanently improved in eleven and temporarily improved in eight cases. A gain in body weight was evident in six, and no influence was apparent in twenty-seven cases. Hemorrhage was lessened in eight cases and uninfluenced in one case. Evidences of systemic toxæmia were noted in fourteen cases. Out of the thirty-three cases there were three apparent cures; thirteen were permanently benefited and were still improving; twelve were temporarily benefited; two were not benefited, and in three the treatment was discontinued too soon to expect any result. Every one of the cases was inoperable and presented a hopeless prognosis. The three cured cases were as follows: Case I.—Round-cell sarcoma of the neck of three years' standing. The patient came under treatment on November 7, 1901, and was suffering constantly. The pain was greatly relieved by the first treatment, and after the sixth treatment it disappeared permanently. Up to the present time the disease had not recurred. According to Dr. William B. Coley, there was no case on record of the permanent cure of a sarcoma of the neck. Case II.—A case of recurrent carcinoma of the right breast with evidences of metastasis in the deep lymphatics of the trunk. The case came under treatment on March 2[illegible] 1902, and up to the present time she had received sixty treatments, directed alternately upon the breast and upon the deep lymphatics of the trunk. The enlarged glands in the neighborhood of the clavicle and in the pectoralis muscle had entirely disappeared, and the patient had gained ten pounds in the past three months. Case III.—A nodulated palpable tumor, probably sarcoma, situated deeply in the lower lumbar and upper sacral regions The case first came under treatment on February 3 1902, and at that time she was suffering a good deal of pain Up to June 7 she received thirty treatments, and was then practically free from pain, and the tumors had been reduced so much as to be no longer palpable. At that time she was operated upon for a tubal pregnancy, and the operating surgeon stated that all that was found to indicate the original growth were three nodules about the size of a pea.

Dr. J. D. Gibson of Birmingham, Ala., said that his experience had been that in superficial cancers the best results were obtained from the use of very soft tubes and close exposures, ranging from seven to ten minutes. In one or two of these cases he had used a high vacuum tube, and while it had caused considerable reaction the cancer did not seem to improve so rapidly as with the soft tube.

Dr. Robinson of Lexington, Ky., said that his experience had been that if there was much involvement of the tissues the soft tubes did not give such good results—in other words, that the soft tube only influenced the superficial tissues.

Dr. N. J. Nunn of Savannah deplored this loose talk about "hard" and "soft" tubes, and suggested that it would be more exact to speak of the penetrating power of tubes, this power to be determined by the power of the tube to penetrate a definite thickness of metal.

Dr. Albert C. Geyser of New York City said that one could not speak with accuracy concerning the penetrating power of a given tube, because this was well known to vary from hour to hour. A valuable and practical way of distinguishing between high and low-vacuum tubes was by the color of the light emitted—green for a high vacuum and blue for a low vacuum or soft tube.

Dr. W. B. Snow observed that it was easy to determine the vacuum of a tube with the static machine by noting the spark gap. If the largest spark gap that could be used were only an inch or an inch and a half, the vacuum in the tube was low, while a spark gap over four inches indicated a high vacuum in the tube. With a coil it was not such an easy matter. It was advisable to use a tube having a large bulb, as the vacuum in such a tube did not change so quickly from the heating of the anode and cathode.

Dr. G. Betton Massey said that if more than he claimed for mercuric cataphoresis were true there would still be an immense field for the *x*-ray treatment of cancer The *x*-ray was easier of application, and would be found particularly useful in cases in which the area was too great for the successful application of a purely local treatment. In recurrent carcinomat of the breast the wide and deep penetration of the *x*-ray should prove especially valuable.

Dr. Robert Reyburn said he believed that the reason the knife failed in the treatment of cancer was that the disease was always diffused beyond the part visible to the unaided eye and the knife, and consequently laid open fresh channels of infection. The treatment of certain cases of cancer by caustic pastes was still popular, because of its far-reaching action, and he believed that the *x*-ray acted in a similar manner, only with the important advantage that it yielded a much better cosmetic result.

Dr. C. R. Dickson spoke of an instrument that had been devised for measuring the penetrating power of a given *x*-ray tube by means of the interposition of a varying number of thicknesses of tin foil.

Dr. SKINNER, in closing, said that he was inclined to agree with Dr. Reyburn that the *x*-ray favorably influenced cases of cancer by exerting an influence on the surrounding cells, whereby the disease was walled off from the rest of the body. All of the cases reported in the paper had been treated with a Morton-Holtz-Wimshurst machine of twelve plates, and the effects had been such as to lead him to hope that still more might be accomplished by a sixteen-plate machine.

The X-Rays in the Treatment of Cancer.—Dr. J. D. GIBSON of Birmingham, Ala., presented in this paper the clinical records of seven cases of epithelioma. He considered the *x*-ray of proper penetrating power, and, when properly used, a specific for malignant growths.

Dr. ROBINSON of Lexington, Ky., believed the only way to conduct this treatment was by the use of a high vacuum tube, and he cautioned against too frequent treatments; twice a week was usually sufficient.

Dr. C. E. SKINNER said that it was extremely important to remember that tubes of different penetrating power were necessary for tumors in different parts of the body. Sometimes a growth would respond well to treatment for three or four weeks, and then would come to a standstill unless a high vacuum tube were substituted.

Dr. D PRESTON PRATT of Chicago said that a simple explanation of the action of the *x*-ray would be found by supposing it to be similar to that of the ordinary electrical current. On the side of the body exposed to the *x*-ray one obtained an acid reaction and on the opposite side an alkaline reaction. Thousands of lines of force were concentrated, and hence the greater the decomposition the greater the change in the tissues. In his own work he was using a low tube on superficial cancer, and by increasing the force of the machine he obtained a greater number of lines of force in a given area, or, in other words, increased the penetrating power of the tube. There was absolute proof that the action of the *x*-ray on the body was due to changes in the ions produced by electrical force. The static breeze should not be used on cancer cases, because it would spread the infection.

Dr. ALBERT C. GEYSER of New York City said that two years ago he had called attention to the advantage of using the static breeze on exposed surfaces.

Dr. GIBSON, in closing, said that he had found the softest ray the most useful in skin cancers, but it required a ray of at least medium hardness to penetrate the body well. He was disposed to believe that the free use of the static breeze in the treatment was dangerous in that it favored the production of sepsis. While the breeze was an eliminator, it also served to increase metabolism, and apparently favored the dissemination of sepsis.

Second Day.—Wednesday, September 3.

Electrotherapy and the St. Louis Exposition.—At the suggestion of Mr. W E. Goldsboro, an associate member of the association, the following resolution was unanimously adopted, and a special committee was appointed to cooperate with Mr. Goldsboro:

Whereas, There is to be held in the city of St. Louis in 1904 an exposition of the arts and sciences of the world as an expression of our advanced civilization; and

Whereas, We understand that the provisions to be made for the exhibit of the progress of electricity will be adequate, and feel that electrotherapeutics deserve special recognition;

Resolved, That the American Electro-Therapeutic Association heartily commends and supports the plans which have been inaugurated for containing an electrotherapeutic display commensurate with the dignity and importance of this branch of electricity.

Epithelioma of the Tongue.—Dr. C. R. DICKSON, of Toronto, Can., read this paper. In it he reported four cases, and raised the question as to whether the ordinary *x*-ray or mercuric cataphoresis was the better. He said that he had not obtained as good results from the *x*-ray in the treatment of this class of cases as in other cases of malignant disease. The chief result was the relief of pain from the employment of mercuric cataphoresis.

Dr. D. P. PRATT said that he had treated four cases of epithelioma of the tongue, and had succeeded in curing two of them. He now believed that the other two had died because he did not know how to treat them. In one of the cases the use of the static breeze had been followed by a rapid spread of the infection, and this led him to insist strenuously that the static breeze should not be used in muscular regions.

Dr. W. B. SNOW said that he had used the brush discharge a good deal for its tonic effect upon open surfaces, and had not met with infection—indeed, it was an excellent antiseptic application. The patient should always be inductively insulated, the discharging rods widely separated, and the wooden electrode insulated by a tapering covering of glass.

Dr. FRANCIS B. BISHOP expressed the opinion that one reason for Dr. Dickson's not having obtained a better effect from the galvanic treatment was that his active pole had too much surface for the amperage employed.

Dr. DICKSON replied that it had not been considered advisable to use general anæsthesia, and it was for this reason that this size had been used.

Some Therapeutic Notes on the X-Rays.—Dr. DICKSON also read this paper. He said that he preferred the static machine and the high vacuum tube, and wrapped the shank of the tube with rubber sheeting to prevent sparking. During the first two weeks of treatment he placed the tube one or two feet from the part to be acted upon, and then gradually lessened the distance to a minimum of six inches. Only in critical cases did he approve of daily treatments, and the average duration of each treatment was ten minutes, although this was occasionally increased to twenty minutes. He avoided producing more than a marked erythema. When the vacuum tube was used in conjunction with a metallic screen the tube should be insulated with rubber sheeting, so as to prevent sparking between it and the screen. Following a suggestion of a writer in a recent issue of the *British Medical Journal*, he had made use of applications of adrenalin solution, and had found that intensified reaction. He had treated with the *x*-ray a case of vascular nævus, and it was gradually disappearing. Various other cases were also described.

Dr. J. D. GIBSON said that he had cured lupus with nothing else but the brush discharge, though he believed with the *x*-ray the cure could be materially hastened. He believed that in the near future carcinoma of the liver would be permanently cured by the *x*-ray. The great problem was to secure drainage, and it was not improbable that this would be attained by cutting down upon the part. The more a case of cancer had been interfered with surgically, the more obstinate would it prove under *x*-ray treatment.

Dr. A. D. ROCKWELL of New York city said that the reason the galvanic current and the *x*-ray relieve pain was that they set up a sort of circulatory drainage, thus diminishing the pressure on the nerve endings. He had used the brush discharge for years, but was of the opinion that it was too frequently employed. He considered the discharge obtained by the use of the converter from the static machine and a step-up process, giving greatly increased voltage, far superior to the brush discharge. In acne he had seen some excellent results from the use of this so-called hyperstatic current, and in a case of xanthoma palpebrarum it had acted admirably.

Dr. W. B. SNOW said that what was known in New York as No. 32 tin composition was the proper substance to use for *x*-ray shields. In closed cavities he made use of the glass shield, and also of specially designed simple glass vacuum tubes, connected with the negative pole of the static machine. He had used the brush discharge with the wooden electrode, and with better satisfaction than Dr. Rockwell had done.

Dr. Willis P. Spring of Minneapolis said that he had lately learned that the soft rubber used by dentists for making artificial teeth is quite opaque to the *x*-ray, and hence is of value as a shield for protecting the tube from short circuiting.

Dr. W. W. Eaton of Massachusetts, said that for over a year he had been using the hyperstatic current, and had found it especially valuable in the treatment of chronic eczema and in the relief of severe facial neuralgias. In cases of carcinoma and sarcoma he favored the use of the galvanic current as well as the *x*-ray. In one case of carcinoma of the liver, treated by a galvanic current of 150 ma. and a clay electrode front and back, the result was good, although the patient could not be said to be completely cured. Each seance lasted fifteen minutes, and was repeated every second or third day.

Dr. D. P. Pratt, speaking of *x*-ray burns, declared that they were due to the fact that microbes from the atmosphere were driven from the surface of the tube into the body. To guard against this it was only necessary to interpose a piece of celluloid, one-sixteenth of an inch thick, between the tube and the body.

Dr. C. E. Skinner denied that this was the true explanation, and added that while it was generally conceded that microbes could not be driven through absorbent cotton one of his patients had been quite badly burned, though the *x*-ray was made to pass through a surgical dressing.

Dr. R. J. Nunn remarked that if it were true that a microbe could be driven in by the *x*-ray, then it must be equally true that medicaments could be driven in in the same way.

Dr. Pratt replied that Dr. Alexander Wiener, a surgeon of Chicago, was at present working in just this line. He had invented a "celluloid cream" as a base, and with it he mixed 10 per cent. creosote. It was found that when this was applied over a tuberculous gland the creosote was driven in by the *x*-ray and the gland was reduced in two or three weeks. Experiments showed that the medicament was actually driven into the body.

A New System for Producing a Slow Alternating Current of Large Amperage for Therapeutic Use.—Dr. Lucy Hall-Brown of Brooklyn, N. Y., described this system, exhibiting the apparatus and citing cases. The apparatus is the invention of Mr. Patten, and has been modified and manufactured by E. A. Callahan of Brooklyn. The system consists in taking any straight continuous current, such as the Edison current, and transforming it into a slowly alternating current of the sinusoidal type, and with a frequency of alternations varying at will from one to fifty per minute. The current can also be transformed into a slow alternating current of a sinusoidal character. The current strength may be varied from zero to 300 or more milliamperes. The apparatus consists of a tub filled with distilled water, and having carbon plates on opposite sides. At the center of the tub is an insulated spindle, which is revolved by clockwork or by an electro-motor. At either end of this spindle is a plate of carbon or metal. By this arrangement the patient is placed upon a shunt circuit. As the revolving plates approach the fixed plates a current is set up in the patient's circuit, and this gradually increases until the nearest point is reached. After passing the terminal plates the current diminishes to zero again, and so on, the direction of the current likewise changing. The clinical effects from the use of the current from this apparatus were interesting, and peculiar, but they had not yet been thoroughly investigated, though they were being studied at the Long Island College Hospital and elsewhere.

Dr. A. D. Rockwell agreed with the reader of the paper that this current would not relieve pain when it was due to a neuritis or any acute or subacute inflammatory condition. His experience with the combined galvanic and faradic currents had taught him that these pains would not be relieved as well as by either the high tension current or the galvanic current alone. On the other hand, he had found it useful in spasmodic conditions. The same would probably be found true of the current from the apparatus now under discussion.

Dr. G. Betton Massey thought this was the best alternator he had ever seen, and the idea of using water to change the strength of the current seemed to be absolutely novel and original. He would expect this current to act well in chronic constipation arising from atony, and in atonic conditions of the uterus and vagina.

Dr. D. P. Pratt said that it was certainly the best instrument of its kind, and he predicted that it would prove more useful than any other similar instrument.

Current Differentiation Illustrated by a Case of Peripheral Neuritis Due to Parenchymatous Degeneration of the Cord.—Dr. A. D. Rockwell of New York City was the author of this paper. The case was presented: (1) because it illustrated a somewhat unusual form of neuritis; (2) as an excellent example of the necessity for careful differentiation, and (3) because of the prompt relief afforded after the failure of all other methods, including the use by others of static electricity. The case was evidently of toxic and central origin and deeply seated. The treatment which he had adopted with complete success was as follows: A cathode of sculptor's clay, three by four inches, was applied to the solar plexus, while the anode was applied by the labile method to the cervical and upper dorsal regions, and occasionally to the left arm. The strength of the current was from 20 to 60 ma., and the seances were of ten minutes' duration and were repeated daily.

Drs. Brower, Eaton, and Massey, in discussing the paper, took occasion to point out that static electricity was so wonderfully convenient of application that there had been a strong tendency in recent years to neglect galvanic treatment.

Dr. F. B. Bishop said that if he were compelled to give up all but one form of electrical treatment he would cling to his old galvanic battery, though constantly making use of static electricity. The action of the galvanic current on the superior cervical ganglia and on the pneumogastric nerve seemed to exert an influence on the entire body. He had often treated localized pain with galvanism, and, long before this pain had been completely relieved, had observed a decided improvement in the general condition.

Dr. J. D. Gibson cited some cases in point, and declared that it was almost impossible to reach deep pains in the lumbar and dorsal regions by means of the static machine.

Some Therapeutic Indications from the Use of the Electric-Light Bath.—Dr. T. D. Crothers of Hartford presented this communication. He said that the sudorific action of the electric-light bath was evidently superior to that of the ordinary hot-air bath. His experience with the electric-light bath had been chiefly among persons suffering from the toxic insanities or conditions resulting from drug-taking. He had given thirty or more baths a week. The bath that he had employed consisted of a room, five feet square and six feet high, lined with tin and lighted by one hundred incandescent electric lamps of sixteen candle power each. The entire body of the patient was exposed to the light in this room, the head being covered with a napkin, because experience showed that the treatment caused a marked drying of the hair. Sweating usually began in from two to seven minutes, and became profuse in from ten to fifteen minutes. The average duration of the treatment was twelve minutes. The regularity and force of the heart's action were increased by the treatment, and this improvement lasted for some time afterward. The patient was allowed to drink water very freely. After the bath, massage was given with hot or cold showers, and the patient then went to bed, the baths being usually given in the evening. The bath was found to promote sleep and diminish the cravings of drug-takers. The particular disorders which seemed to be influenced by the bath were neuritis, myalgia, and extreme nervous irritation. Arteriosclerosis, so common in this class of cases, appeared to be materially benefited by the electric-light bath. That the good effects observed were largely dependent upon the electric light was shown by the inferior results obtained when the hot-air bath was used with showers and massage. The psychical effect of the treatment, moreover, was not to be despised. He had not examined the blood with reference to leucocytosis, but the elimination of urea had been invariably augmented by the bath.

Dr. W. B. Snow said that in the apparatus employed by Dr. Crothers the therapeutic effects were evidently due to heat. Light, as a therapeutic agent, undoubtedly had a great value, but Finsen, in Europe, and Dr. Margaret A. Cleaves, in this country, had shown that to secure this effect of light our methods must be modified. He believed that the glass bulbs of the electric lights cut off a good deal of the therapeutic action of the light. If one were aiming at the therapeutic effect of heat, then higher temperatures should be used than in Dr. Crothers' cases.

Dr. Robert Newman of New York City, said that this light treatment was nothing more than an imitation of the effect of the sun, and it was well known that life could not be sustained without the sun. He believed the electric light was destined to play an important part in our therapeutics.

Dr. M. M. Johnson of Hartford said that he had observed the work of Dr. Crothers with the electric-light bath, and was positive that part of the effect was due to the light. In an ordinary hot-air bath, one does not see, as in the electric-light bath, little spots appear on the skin, indicating a profound effect on the cutaneous and nervous systems.

Dr. Charles O. Files of Portland, Me., spoke of the use of the electric light in the treatment of tuberculosis. Here the whole person, including the head, should be exposed. He made use of a bath having two arc lights and thirty-five incandescent lamps, arranged so that they could be used collectively or separately. He had found in some tuberculous cases in which coughing was so incessant as to make sleep almost impossible that the ozone, or something else, in the bath, promoted sleep very remarkably and also caused increased secretion.

Dr. J. D Gibson said that he had been using the electric arc lights for several years in the treatment of tuberculosis. He used arc lights of eight thousand candle power in a room measuring 16½ by 6 by 8 feet. It was necessaryto protect the eyes from the glare.

Dr. Robert Reyburn remarked that while we all knew the effect of the sun's rays, experiments published about a year ago showed clearly that the transparency of the human body to the sun's rays was but little known and appreciated.

Dr. Crothers, in closing, said that when there was any hyperæsthetic condition of the body the affected part became intensely red under the action of the light bath. For a day following the bath there was a feeling of distinct exhilaration and contentment.

Some Obstacles to the Progress of Electrotherapeutics.—Dr. Charles O. Files of Portland, Me., was the author of this paper. He said that one of the first obstacles encountered was the dense ignorance prevailing even among physicians concerning medical electricity. Again, the rapid strides of antiseptic and aseptic surgery had also retarded the progress of electrotherapy, not to speak of wilful discouragement emanating from certain surgeons. Unfortunately, electrotherapy had been impaled upon the horns of pessimism, on the one hand, and optimism on the other. The remedy was to be found in the general diffusion of knowledge among physicians and lay men relative to the curative properties of the electric current.

A Portable Electric Apparatus for Medical Use.—Dr. Robert Reyburn of Washington, D. C., exhibited this apparatus. It consisted of a wooden box, about six inches square, containing five dry compound cells, each made up of three cells, thus making the total voltage 22.5. The batteries, which cost forty cents each, are made for small electric-light outfits. According to the resistance employed, the apparatus would yield a current of thirty or more milliamperes. Instead of the expensive and delicate milliamperemeter, he used in connection with this portable apparatus Queen's galvanoscope. This can be calibrated experimentally with sufficient accuracy. One milliampere deflects the needle 10°. In place of the water rheostat he makes use of a rod of carbon, having a resistance of about four thousand ohms. This carbon rod is specially made for electrical measurements, and has a sliding metallic collar, by which rhe current is readily passed through varying lengths of the rod.

Newman's Portable Galvanic Battery.—Dr. Robert Newman of New York City described his apparatus. He said that he originally designed this battery years ago, but had more recently modified and improved it. All parts of the battery are visible, and the apparatus is portable. The cells are empty in transit, and are only filled at the place where the battery is to be used. The ordinary acid bichromate fluid is carried in a concentrated form, and is thrown away after the battery has been used. A dilution of acid of one in ten or one in twenty is sufficiently strong, and two and a half ounces of bichromate of potassium are added for each ounce of the battery fluid. The battery consists of twenty hard rubber cells, with zinc and carbon rods for the elements. If desired, the battery can be used with only ten of the cells filled. The apparatus is provided with a simple and convenient current selector.

The Diffusion of Iodine by the Electric Current.—Dr. M. F. Wheatland of Newport presented this communication. The paper contained a description of experiments carried out with the idea of clearing up certain misunderstandings regarding the diffusion of this substance. These experiments showed that iodide of potassium followed the well-known physical laws governing electrical decomposition, and that there was no reason for believing that iodide is projected into the tissues by the *positive* pole, as asserted by some writers.

Dr. Robert Newman insisted that cataphoresis was only one part of electrolysis. He said that in the electrolysis of iodide of potassium the positive pole would attract the iodine and the oxygen of the acids, while the negative pole would attract the base, the alkalies, and the hydrogen.

Dr. D. P. Pratt said that he had succeeded in driving in iodine with the positive pole, but it had returned immediately.

Arthritis Deformans.—Dr. Francis B. Bishop of Washington, D. C., presented this paper. He said that the diet of these patients should consist of beef, mutton, and similar proteids, with very little bread and with milk and eggs and water in abundance. Static electricity, in the form of sparks, to the joints, or, as some prefer, the wave current should be employed. Where there was effusion into the joint he applied the galvanic current in such a way as to cause a good-sized blister. Many cases had been treated by him with more or less success by electricity alone, but no severe case of long standing had been cured by electricity alone. The speaker said that, in spite of authoritative statements to the contrary, he was free to declare that arthritis deformans, even when advanced, could be cured by electricity and proper dietetic treatment.

Dr. Snow said that he had treated upward of thirty cases of rheumatoid arthritis, many of them with excellent success. It had been his uniform practice to put these patients on a meat diet He had not used the galvanic current, but was free to admit that Dr. Bishop's results with that current were better than he could have obtained from the static machine alone. He founded his prognosis on whether a skiagraph showed the cartilages to be destroyed. The origin of the trouble was still a moot question, but the indication for treatment was clear, *i. e.* improve the general nutrition, and this electricity would do most effectually. At the present time he believed that the *body* hot-air treatment was of benefit in these cases, though not sufficient by itself. The pain could be very promptly relieved by the brush discharge

Dr. D. R. Brower of Chicago said that he had long ago been compelled to take the position that these patients require a nitrogenous diet—an abundance of red meat. He had also found it desirable to exclude sugar, and, to a considerable extent, sugar-producing substances.

Dr. C. E. Skinner believed that the disease originated in some central nervous disorder. He agreed with what had been said about the diet, including that regarding the exclusion of sugar. The dry hot-air body treatment had proved, in his hands, a valuable adjunct to electricity, though the local hot-air treatment was useless.

Dr. N. C. Nutting of New Hampshire said that he had found starch and sugar very detrimental to rheumatic subjects. It had been his habit to have them eat freely of meat and to drink very large quantities of water.

Third Day.—Thursday, September 4.

The Relation of Psychic Suggestion to Electrotherapeutics.—Dr. Maurice F. Pilgrim of Boston discussed in this paper the philosophy of the healing of disease and the relation to true medical treatment of such fads as Christian Science. Great stress was laid upon the important part played by the *vis medicatrix naturæ*, and a word of caution was uttered against hasty and enthusiastic generalizations and deductions from observations of the supposed effects of medicine and other means of treating disease. Emphasis was laid upon psychic suggestion as an important adjuvant to electrotherapy, and the profession was urged to rescue this important means of relieving the sick from the ignorant and unscrupulous. The absurdity and mischievousness of the doctrine that psychic suggestion could not be made operative unless the person to be treated renounced belief in all other modes of treatment were dwelt upon, and its perniciousness made clear. It was the author's firm conviction that the relation between psychic suggestion and electrotherapeutics was natural and should be a closed one. In closing the lengthy discussion which this paper elicited, Dr. Pilgrim said that no one believed more thoroughly in electricity than he, yet he was far from believing that it could cure all cases. By using psychic force in connection with electrical treatment without saying a word to his patient, he had been able to get better results than from electrotherapy alone.

Illustrative Cases in the Cataphoric Treatment of Cancer.—Dr. G. Betton Massey of Philadelphia presented this communication. In it he reported a number of cases to illustrate the efficacy of this method of treatment. Some of the clinical records were accompanied by photographs showing clearly what had been accomplished.

Officers Elected and Place of Meeting.—*President*, Dr. C. R. Brower of Chicago; *First Vice-President*, Dr. Maurice F. Pilgrim of Boston; *Second Vice-President*, Dr. C. Frank Osman of Boston; *Treasurer*, Dr. R. J. Nunn of Savannah, *Secretary*, Dr Clarence E Skinner of New Haven; *Executive Council*, Drs. F. H Morse and Charle O Files. The next annual meeting will be held at Atlanti City in September, 1903

Therapeutic Hints.

Atrophic Rhinitis.

℞	Menthol		gr xx
	Aristol		ʒss
	Benzoinol		ʒi

M Sig. Use in atomizer.

—J. C Patterson

Insomia of Neurasthenia.—

℞	Camphor. monobrom		gr ii
	Ext. cannabis indic		
	Ext. hyoscyami	āā	gr. ⅓.
	Ft. pil. No i.		

Sig. Two to five pills daily.

Debove and Gouri

Burns.—Robert T. Morris says that in extensive burns of the second degree, accompanied by shock, he places the patient, clothes and all, into a bathtub of hot water, injects morphine hypodermatically and anæsthetizes the patient with ether before removing the clothing or dressings. This avoids pain and lessens the degree of shock

Fruits.—The relative value and importance of fruits are said to be according to the following order: Apples grapes, bananas, oranges, peaches, pears, apricots, pineapples, plums, strawberries, raspberries, blackberries.—*Medical Times.*

Pruritus Ani.—F. S. Meara (*Merck's Archives*) reports two cases of violent itching of the anus and vulva relieved by the local application of a strong solution of suprarenal extract, repeated at intervals of twelve hours.

Hereditary Syphilis.—Jacobi states that the infant should be nursed by its mother, but never by a wet nurse; treatment should be carried out for two years, but intermittently. The best medication consists of calomel $\frac{1}{8}$ gr. three times daily for weeks, iron if anæmia be present, mercury with chalk in doses of $\frac{1}{6}$ to $\frac{1}{3}$ gr. Mercury does not affect the mouth and bowels of the infant as readily as those of the adult. Inunctions are valuable, but may irritate the skin. In extensive skin lesions bichloride baths, 1-1000, act well. Iodides are not necessary in the secondary stage, but are useful in sphyilis tarda. For iodism give chlorate of potash and atropine. Iron and arsenic are the drugs for malnutrition.

Frequent Micturition will often be relieved by the use of hyoscyamine sulphate in doses of 1-250 of a grain every hour.—*The Surgical Clinic.*

Pruritus Vulvæ.—A 10 per cent. guaiacol vasogen applied on cotton at night, and repeated for several evenings, will cure pruritus vulvæ in a short time.
SELLIGMANN.

Dysentery.—G. B. Richmond recommends twenty grains of sublimed sulphur combined with five grains of Dover's powder as effecting a cure in dysentery. In patients so treated there was no tendency to relapse or to chronic diarrhœa, alternating with constipation. This method is considered by him superior to ipecac.

Rigidity of Cervix.—Partridge says that in a rigid cervix nothing acts so well as a hypodermatic injection of $\frac{1}{4}$ of a grain of morphine and 1-150 of a grain of atropine. This is usually followed by a sleep of two or three hours, and when the patient awakens the pains begin, the cervix relaxes and labor proceeds. No ill effects seem to follow this plan of treatment.

Heat Flashes.—For the night attacks of heat and sweating observed so frequently at the menopause, Gottschalk advises the use of hot saline baths at a temperature of 42°C., lasting for about twenty minutes and to be taken every evening before bedtime.

To Preserve Suprarenal Extract.—C. W. Heitzman states that the fraction of a drop of formaldehyde to an ounce will preserve solutions of suprarenal extract, cocaine, and eucaine without rendering them irritating.

In Coryza, hay fever and allied conditions, James E. Talley considers cinchonine sulphate, in four to six grain doses three or four times daily, a most useful drug.

Surgical Suggestions.

Vesication by Chloral Hydrate.—Bonne states that rapid vesication may be produced by the use of chloral hydrate. A layer of the drug is spread over diachylon plaster, using about forty-five grains for a surface five or six inches square; it is then applied to the skin, over which vaselin or oil of sweet almonds has been previously applied; in about fifteen minutes the patient experiences a sensation of heat, which soon assumes a burning character; the plaster is then removed and the area covered with cotton; at the end of twenty or thirty minutes a blister is formed, and the patient falls asleep.

Injection Treatment of Piles.—(1) Inject only internal piles, (2) The solution of carbolic acid should not exceed 10 per cent; (3) Do not repeat the operation under a week; (4) Inject only one or two minims into each tumor; (5) Inject not more than two piles at any one time; (6) Promise relief only, and not a radical or a permanent cure. —*George W. Gay.*

Dressing for Wounds.—My experience has led me to rely fully upon balsam of Peru or iodoform as a dressing for wounds.—*Banker.*

To Boil Catheters.—M. W. Herman states that boiling silk catheters in saturated solution of ammonia sulphate prevents them from becoming cracked and rough. Boiling for from three to five minutes causes complete sterilization, and after removal they may be used immediately, because solutions of ammonium sulphate are non-irritating to mucous membranes..

The Umbilical Cord.—Budberg advises wrapping the umbilical cord in cotton soaked in alcohol. This acts as an efficient antiseptic and causes drying of the cord.

Eneuresis.—In the involuntary micturition in children Lydston recommends the urethral sound, deep injections of strychnine in the lumbar region, or urotropin—the first to relieve hyperæsthesia, the second to control the neurosis, and the last to correct the vesical catarrh.

A Hot Poultice should be hot, moist, light in color and weight, applied to relieve inflammation, draw pus to surface, etc. It should never be allowed to get cold on the patient; should be put between folds of gauze or muslin; lubricate skin; test heat against your cheek, remembering that the interior is warmer than the exterior. Cover with absorbent cotton and bandage loosely. Apply poultice gradually by allowing it to slip from the hand. Make poultice two inches larger all around the inflamed area. Discontinue use of the same as soon as tissues are softened and pus evacuated.—*Hanna Kindborn.*

Tincture of Soap has been recommended as the best medium for sterilizing edged eye instruments. It not only cleans off the blood or pus, but preserves the edge. The instruments should be wiped and placed in the tincture for fifteen minutes, then wiped again and placed in boric acid solution before the operation. After use they should be replaced in the tincture and wiped and put away.—*The Medical Times.*

In Cellulitis of the hand or foot an injection into the abscess cavity of 95 per cent. carbolic acid, followed by 95 per cent. alcohol, gives good results.—*Sargent.*

After Suturing a wound of the bladder, fill the viscus with sterilized saline solution, to observe whether there is any leakage.—*International Journal of Surgery.*

In Intracapsular Fracture of the Femur Thomson advises nailing the head to the shaft with a silver nail.

Surgeons have now quite generally abandoned the procedure of washing out the pleura after operations for empyema. Washing out does not seem to shorten the period of recovery, and it may, if repeated, cause a tendency to the establishment of a permanent fistula. It may also interfere with the formation of adhesions, thus preventing the union of opposite layers of the pleura.—*International Journal of Surgery.*

The Bacteriology of Epidemic Diarrhœa and Its Differential Diagnosis from Other Similar Diseases.—M. H. Gordon concludes that, from an examination of the literature of the subject, one fact comes out very clearly, and that is, that a more precise knowledge of the relative abundance and the attributes of bacteria occurring in the *normal* intestine would be of great value in enabling us to attach their due relative significance to many of the observations that have been made in cases of diarrhœa. Again, the relative abundance of the pathogenic organisms that have been found to occur in the dejecta in diarrhœa is a subject about which too little is known. Accurate information would also be welcome in regard to the exact relationship of various pathogenic members of the great coli-typhoid family. Hitherto, most attention has been paid to B. coli communis and B. typhosus, but enteritis, as a whole, seems to be associated with various other members of the family, and further knowledge of their relations and characters may result in more accurate perceptions, both of their effects, and of the ways to counteract them.—*The Practitioner.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 13, 1902:

	Cases.	Deaths.
Measles	47	4
Diphtheria and croup	189	33
Scarlet fever	97	6
Smallpox	6	3
Varicella	7	..
Tuberculosis	233	131
Typhoid fever	142	18
Cerebrospinal meningitis	..	1

A Good Physician.—He had completed his long course of study; had worked hard; and stood well in his class. But, as he listened to the inspiring words of the speaker who delivered the address to the graduating class, he was bathed in cold perspiration, on account of fears that his thread-bare trousers' seat might become apparent as he ascended to the stage to receive the parchment roll for which he had so earnestly labored.

A few hours later he emerged from the banquet hall, full of enthusiasm and poor claret. Then and there he registered a vow that the cold, proud, sickly world should find in him a foeman worthy of its steel. He located in a small town and waited for his longed-for practice. The cold world, however, seemed unaware of the existence of such a foeman as he; for no such knowledge was made apparent either in show of steel or coin; and the young doctor was almost in despair. But at last his first call came The old doctor across the street being out of town, a man taken suddenly ill, thinking a young fledgling better than nothing, sent for our young physician. He rapidly recovered; and, being in a grateful frame of mind, not only paid his bill, but spoke kindly to his friends of the doctor who, by his intelligent, and conscientious management of his case, had shown true merit. Then other patients came; and the start was really made. From this nucleus his practice gradually extended. The progress was slow at first, but some of his patients paid their bills. He roomed in his office. Oatmeal and soft boiled eggs are not expensive; and then, you know, it is possible to buy coffee cheap in price as well as taste. As winter approached he became the proud possessor of a new, warm overcoat. It was not fur or silk-lined, to be sure, but he found it very comfortable. One evening he had an office patient. The man greeted him as "Doc"; told him "he had come miles to see him, and was very sure he had at last found a doctor "who could hit his case." The doctor prescribed. The patient thought the fee ridiculously small, and insisted upon its being doubled. Unfortunately, he had "left his money in his room," but with a promise to call the following morning and pay his bill, he departed. The new overcoat eloped with him; and the doctor did not get his fee.

He attended a family of six children through an epidemic of scarlet fever, with its many complications. The parents of these children were profuse in their expressions of gratitude for the doctor's services. "Every cent of his bill would be paid." They would "do without clothing, if necessary, to do this." A few months later the doctor asked the father for a small payment on the bill. The man was "very sorry," but work was scarce, expenses high, and he was "awful hard up" just then. The following day, the doctor met the whole flock at the circus. The children's faces were embellished with liberal applications of gingerbread and painted candy, and the doctor never again asked this man for his fee.

He called one day upon a woman, to remind her that he might be able to use a little money. She was extremely sorry, also, that she could not help him, but "she had recently purchased a piano for Clementina, and was paying for it on the installment plan." She asked Clementina to "play something for the Doctor." As the fair maiden raced up and down the switch-board in search of the Lost Chord, he wondered why he was ever born At last the suffering seemed to have subsided, but when the proud mother suggested that Clementina "play it over again," the doctor was suddenly seized with a pain and made his escape. In his happy deliverance he found his only fee

After a time, his assets in cord wood, maple syrup, yellow dogs and, perhaps, a Thomas cat or two, seemed to warrant his taking unto himself a wife She proved a helpmeet, indeed. He always found his stockings darned His buttons always were intact; his office "spick-span" clean; and meals were always ready at the proper time. This happy pair, at the outset, resolved that their wedded life should be a grand success; one long, sweet love song. Misunderstandings and mistakes, of course, did happen, but, through the existence of an abiding love and mutual confidence, they were readily repaired. Their first fee was a boy. They named him John.

The essential requirements for a successful career in medicine are, a good groundwork of knowledge regarding theory; thorough training in methods of application; a fixed purpose; honesty, tact, and good common sense. Happy is the man who, in addition to these qualifications, has the gift of inspiring in his patients courage and hope; and leaving with them, in his round of calls, a ray of sunshine.

In this respect our young doctor was, indeed, fortunate. No matter how worn and tired he might be, he endeavored always to take with him, not only pills and prescription blanks, but a goodly fund of sunshine.

One dark, cold night he was called to a little child. His day's work had been hard. He needed rest. But when that night he changed tears and sobs to grateful smiles, and the little girl afterward, in frequent illnesses, always insisted upon having her "good doctor," he felt well repaid for his sacrifice. There came a time when his sunshine was dimmed by tears. The poor little tired sufferer was sinking into her last sleep. With a last conscious word, a last smile for her "dear good doctor," her little spirit took its flight; and now, perhaps, she fills some bright and radiant star with sunshine.

As years went by, our doctor grew in knowledge, skill, and better judgment. He dispensed, not only powders and cathartics, but kindly words of good advice, and many timely warnings. He often found in the loosening of his own purse-strings the surer way of relieving some poor, sorrowing soul of heart strain. He had no need to boast. He simply did his best, and others saw this. He did not pray; he did not preach; but dared to act, and dared to help; he dared to tell the truth; and yes, he swore when necessary, but when this doctor used an oath, he always swore sincerely.

He lived a long and useful life, full of good deeds and helpfulness to others. At length, his life's work being done, his burden dropped; and he sank into a calm, peaceful, dreamless sleep; to awaken—I know not when, I know not where. But, I believe, for every noble, honest man, for every truly, good physician, there, somewhere on the other side awaits no less a fee, than grateful, everlasting sunshine.—*Frank H. Bartlett, M.D., Olean, N. Y.*

The Organism of Variola and Vaccina.—Ishigami believes that, as the result of an investigation carried on at the Imperial Japanese Lymph Station of Osaka since 1893, he has discovered the causative agent of variola and its congener vaccina. A study of the bacteria present in variola lymph, crusts, glands, etc., of human and bovine origin, did not reveal any specific organism, but sections of vaccination sores, human and bovine lymph, and crusts all contained constantly large numbers of a distinct species of protozoa. This organism was also found to be present, during the eruptive stage, in the blood and organs of vaccinated animals. It consists of a round or oval greenish cell with a nucleus, and in the younger stages has the powers of amœboid motion. Its propagation is affected in two ways: The younger organism multiply by fission, but after having reached a certain degree of development, it forms cysts from the contents of which numerous sporozoites arise by fission. The sporozoon may be artificially cultivated on a medium consisting mainly of epithelial cells of unvaccinated animals. Calves inoculated with such a culture in two or three days develop vesicles accompanied by a rise in temperature, and in every particular corresponding to those produced after vaccination with ordinary bovine lymph. These vesicles contain the same organism, and calves inoculated in this way acquire complete immunity to subsequent vaccination with cow lymph. Both variola and vaccina are due to this same organism, since it is found in the crusts, lymph, and infected tissues of both, and when cultivated from either, produces similar manifestations. The form and properties of the organism greatly resemble those of the Microsporidium Bombycis, but the latter forms spores with polar bodies which have not yet been demonstrated with certainty on the sporozoon in question. —*Centralblatt für Bakteriologie.*

A Case of Quintuplets.—The *Sei-I-Kwai Medical Journal* a trilingual paper published in the land of the "rising sun," contains in a recent issue an account of the birth of quintuplets, which occurred in Japan in the practice of Drs. M. S. and M. U. Sato. The woman, who had previously borne eight children, had been apparently pregnant for eight months when labor ensued, but the abdominal enlargement was much greater than it had been at full term in previous pregnancies. The first fœtus—a boy—was born at 8 P.M.; after four minutes a second fœtus—a girl—was born; after another five minutes the third fœtus—a boy—was born, followed by a common placenta belonging to the first two children. After another five minutes a fourth fœtus—a girl—was delivered by the foot, and common placenta for the third and fourth children was expelled. The medical men, thinking that their task was over, examined the abdomen, but were surprised to find that there was still something in the abdomen, and, after some little difficulty, a fifth fœtus was delivered, followed by its placenta. The entire time occupied by the delivery of all the children was thirty-five minutes. They all died within two days.

Hospital for Consumption in Colorado.—A modern' splendidly-equipped hospital for tuberculous patients is to be given to the State of Colorado by Lawrence C. Phipps, in memory of his mother, Mrs. Agnes Phipps. The building of the institution will be begun in the early fall. The property consists of 160 acres, forty to be used for the present buildings and the remaining 120 will be held by Mr. Phipps at the disposal of the sanatorium whenever needed. The Denver staff will be Drs. Thomas J. Gallagher, George W. Holden, William H. Bergtold, and Carrol E Edson. The institution is to be called the Agnes Memorial Sanatorium, and will be arranged on modern sanitary ideas, with one large administration building and groups of cottages. One of its features will be an elaborately-equipped laboratory for the conducting of investigations and study of the disease. The institution will not be a purely charitable one, for patients will be expected to pay, when possible, and preference will be given to those from western Pennsylvania.

The House Fly as a Bearer of Disease.—Dr. J. Manning, in the *Journal of the American Medical Association*, May 17, shows that the fly is a direct factor in the transmission of the microorganisms of wound infection. Captive flies were allowed to crawl over dressings from infected wounds, over pus from a case of salpingitis and over bronchitis, sputum. They were then carefully transferred to culture tubes and allowed to come into contact with the various media. During the experimentation forty-four culture tubes were subjected to fly infection; of this number forty-one tubes showed the colonization at the end of forty-eight hours, three tubes remaining apparently sterile. Pure cultures of the following were obtained: Bacillus pyocyaneus, staphylococcus pyogenes aureus, bacillus prodigio—abdominalis, bacillus coli communis, bacillus prodigio—sus, sarcina aurantiaca, sarcina alba, molds, and fungi.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 13, 1902:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.

RATIONAL OR DIETETIC TREATMENT OF "BRIGHT'S DISEASE" CONTRASTED WITH SURGICAL INTERVENTION.*

By WILLIAM HENRY PORTER, M.D.
NEW YORK.
PROFESSOR OF PATHOLOGY AND GENERAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

WITHIN the past two years the proposition to cure chronic "Bright's disease," so called, by operative interference has been brought prominently before the profession. In view of this fact, it occurred to me that a discussion of the possibilities of operative interference and of scientifically-applied medical therapeutics in "Bright's disease" might be both interesting and profitable.

Scientific therapeutics calls for a method of treatment that has for its aim not alone the removal of symptoms, but the elimination of all the etiological factors entering into the production of the pathological lesions. It must also aim to remove the pathological lesions and bring about as nearly as possible a normal state in the organs implicated.

To comprehend fully the treatment of "Bright's disease," we must have a clear conception of the anatomy, and also the physiological functions of the renal glands. The same is true as regards the etiological factors that enter into the production of these lesions, their pathology, and symptomatology.

Without going too deeply into the histological structure of the kidneys, it can be stated briefly that these organs are composed of two distinct kinds of tissue; the epithelial elements, and the connective tissue substance group. The latter includes the basement substance upon which the epithelial cells rest, and the intervening or intertubular connective tissue, in which are found the blood vessels, nerves, and lymphatics. All of the several structures enumerated enter into the formation of that portion designated as intertubular.

It should be remembered that, to a considerable extent, this intertubular tissue is composed of two kinds of cells; namely, those which have an active function to perform and those which are of a lower order and simply act as connecting cells or fibers that bind the whole structure together.

The functions of the two portions may be briefly stated as follows: The vascular portion, and especially that which constitutes the glomeruli of Malpighi is for the discharge of the water and the inorganic salts held in solution, while the intertubular portion of the vascular areas brings the proteid elements and the oxygen contained in the blood into close relation with the attached surfaces of the epithelial cells lining the uriniferous tubules. As these two substances, the surplus and the utilized proteids, and the oxygen pass along in the blood current of these intertubular blood vessels, they are, as it were, constantly hard pressed against these epithelial cells, that constitute the tubular portion of the renal glands. In bringing about this action, it is highly probable that the kidney, taken as a whole, contracts and expands thus, as it were, pressing the contents of the blood vessels into the epithelial cells, and enabling them to effectually perform their function. A word of explanation relative to the two terms, utilized and non-utilized proteids, may not be without profit at this point. The utilized proteid is that which has passed through the various structures of the body, and, for a time at least, acted as an integral part of the various proteid tissues. The unutilized being that portion of the proteid absorbed from the alimentary tract in excess of the absolute demands and needs of the system, and which must be eliminated from the body, as the carrying capacity of the blood for proteids is a limited one. With this understanding of proteids, it is clear that when the oxygen and the proteids are drawn into the protoplasm of the cells in which oxidation occurs, the oxygen now being released from its previous combination with the hæmoglobin that brought it to the cell protoplasm, at once attacks both the utilized and the non-utilized proteid molecules. Under normal circumstances, and if the oxygen supply is sufficient in quantity, the proteid elements are broken up by a process of oxidation reduction with the production of the catabolic bodies common to the urine, such as urea, uric acid, creatine, water, and carbon dioxide. The first four joining with the water and the salts eliminated through the glomeruli of Malpighi to form the urine, the carbon dioxide, on account of its strong affinity for an alkaline medium, drops back into the blood stream, to be finally expelled from the system by the functional activity of the structures constituting the lungs. The water eliminated through the filtrative process carried on in the glomeruli of Malpighi represents that portion of the water which is taken into the system under its own form, while that which enters through the epithelial cells represents that which is formed as the result of the oxidation reduction of the proteid molecule in the renal epithelial cells. The former enters the lumen of the tubules at its very beginning, and by its constant descent acts upon the excretory cells as a suction force, the same as is known to be the case in the Sprengle's air pump, and thus helps to draw into the lumen of the uriniferous tubules the products of oxidation reduction, that are formed either in the epithelial cells of the kidneys, or at other points in the body. The absence of oxidation reduction products in the blood to any considerable extent, and their abundance in the urine, point strongly to their formation in the renal cells. The water formed by this oxidation reduction in the epithelial cells enters the lumen of the uriniferous tubule below the glomerulus of Malpighi or at its point of formation, and helps to hold the other oxidation products in solution in their passage from the protoplasmic structures. In this peculiar Sprengle-air-pump-like action, it is highly probable that the constant contraction and expansion of the renal glands plays a very essential part.

Another very important point to be considered in connection with the function of the kidney and the production of the pathological lesions in these organs is the battle which is constantly going on between the higher, or noble, cells and the lower, or ignoble, cells, which is most accurately described as follows by Metchnikoff, in his admirable article entitled "What Is Old Age?" (*St. Petersburg Novisti*).

---

*Read before the Lehigh Valley Medical Association, at Easton, Pa., July 10, 1902.

According to Metchnikoff, "Every organ of our body is composed of two kinds of cells—common and, as it were, noble cells. The noble cells determine the peculiar functions of the organs. . . . The common or ignoble cells do not differ from one another; they are identical in all the organs, and their function is to connect and hold together the noble cells.

"Between these two kind of cells there goes on an incessant struggle. The noble cells are stronger, and for a long time they prevail, *i.e.* they successfully resist. But eventually the struggle exhausts them, and the preponderance passes to the common cells. This signalizes the beginning of old age. The noble cells are crowded more and more, the common ones growing in size at their expense and interfering with the functions of the organs. Hence the abnormal diseased appearance of the organs, and the increased difficulties in the way of living. Ultimately the performance of the functions becomes entirely impossible, and we have death."

Metchnikoff gives the term *macrophagi* to the connective-tissue cells, while he calls the noble cells —epithelia and leucocytes—*microphagi*.

This theory can be applied in a double sense in elucidating the production of our renal lesions. First, between the epithelial and the intertubular structures, as Weigert did in 1897, and which was accepted by Cohnheim and C. Wagner, which was to the effect that the connective-tissue proliferation is, in most cases, secondary to and excited by destruction (degeneration) of the renal epithelial elements; and, second, that the macrophagi or ignoble cells of the intertubular tissues are, by their very nature, constantly contending with the microphagi or noble cells of the same or connective tissue for the supremacy. Hence, in many instances where the noble cells are inherently weak, trivial causes will cause a rapid proliferation of the connective tissue between the epithelial structures.

So long as the work imposed upon the renal glands is not too great, and the nutritive supply is of the right kind and quality, the various structures of the kidney will maintain their normal integrity. The microphagi will hold the ascendancy over the macrophagi cells, and the organs will continue to fully perform their function. Under such conditions no pathological changes can be produced. On the other hand, increase the work of these glandular structures, or decrease their nutritive supply, and sooner or later the ignoble cells will gain the ascendancy over the noble, and then retrograde changes will follow, both in function and in structure. One or both of these conditions, operating either singly or in combination, is the cause, and the only cause, of all our renal affections, commonly classed under the generic term "Bright's disease."

When for any reason there is insufficient supply of oxygen, or the amount of the proteids to be oxidized in the epithelial cells is augmented beyond the oxygenating capacity of the system, there will of necessity be imperfect oxidation reduction, or, as occurs in some instances, a portion of the proteid molecules will be isomerically transformed in the protoplasm of the excretory cells of the renal tubules, and eliminated as such into the lumen of the uriniferous tubules. In the former instance and in the milder forms of incomplete oxidation of the proteid elements, there is simply a reduction in the output of the urea with a corresponding increase in the uric acid; in the more severe conditions there will be added to the above-enumerated change in ratio of urea to uric acid, various products indicative of a still more incomplete oxidation reduction of the proteid elements, such as oxalic acid, lactic acid, glucose, etc. In the latter example, or in that condition in which the proteid molecules are not reduced at all, the albuminous substance which has been drawn from the blood into the epithelial protoplasm is then, as before stated, transformed isomerically within the cell, and excreted therefrom directly into the lumen of the uriniferous tubules; not as serum albumin, as was formerly taught, but as one of the many isomeric forms of albumin found in the urine. Thus it becomes clear that by a close and careful study of the urine we are placed in absolute possession of the perfection or imperfection of the system, so far as its ability to transform the proteid molecule is concerned.

The anatomical changes resulting from increased work and defective nutrition are of two principal forms; the one implicating the epithelial structures and the other the so-called intertubular tissue. The lesion may be most marked in one or the other of these two portions, or it may be about equally intense in the two portions. If the anatomical change is confined chiefly to the epithelial structures, it is called a parenchymatous lesion; if it is chiefly in the intertubular portion, it is called an interstitial lesion, and where both are about equally involved it is designated a diffuse lesion. These three common forms may be further subdivided, both anatomically and clinically, thus increasing the number and variety of the lesions that can be recognized during life, and all are produced without any of the changes commonly classed as inflammatory.

This does not imply, however, that there is no such condition affecting the renal structures as an inflammatory process under the common term "Bright's disease," for there is occasionally produced such an intense determination of blood to the renal capillary system so toxic in its composition, that the vascular structures undergo all the changes common to a true inflammation. When this occurs the condition commonly classed as an acute exudative or diffuse nephritis is produced, and it is the only form of renal lesion to which the term *nephritis* should be applied. This form of lesion, however, is exceedingly rare as compared with all the other forms, which are in no sense inflammatory in their nature.

With this brief outline of the histology and functions of the renal glands before us, it is easy to analyze the etiological factors that tend to produce the lesions commonly classed as "Bright's disease." The conditions that will cause an increased amount of work to be thrown upon the epithelial cells of the kidney, and that will interfere with their normal nutrition, are, first, the taking into the system more proteid substances than the system needs. If more proteid material is absorbed than can be used, it must be eliminated, because, as we have already seen, the capacity of the blood to hold proteids in solution is a limited one. Hence, the overcharging of the blood with proteids indicates that the epithelial cells of the kidneys must take up these substances from the blood stream and eliminate them in some isomeric form, or else they must be oxidized into perfect or imperfect catabolic bodies, and in this form be eliminated from the system. If the oxygenating capacity be sufficiently great, oxidation reduction will occur, if not, isomeric transformation occurs, and some one or more of these isomeric forms of albumin appear in the urine. The latter example is well illustrated by the experiments in which an excessive amount of egg albumen is ingested, following which albumin quickly appears in the urine. Not because the egg albumen is absorbed and discharged as such in the urine, but because there is an active digestion with a rapid peptonization of the egg albumen, which, in turn, is followed by the absorption of more peptone than the system has use for Hence, the surcharging of the blood with albumins, and to a degree that exceeds the possibilities of the system to reduce the proteids by oxidation, an isomeric form of albumin appears in the urine as an excretory product of the renal cells—an excretory product, because the albumins are non-diffusible through the blood vessels. With this explanation, it can be asserted that the transitory presence of albumin in the urine may indicate simply and only that the human organism is being supplied with more albumin than it can utilize. Therefore, it can further be asserted that an excess of oxidation products in the urine, and even the presence of albumin in the urine, does not of necessity indicate that the patient has a renal lesion, but it does indicate that one will follow sooner or later if this abnormal condition is not corrected. Excess of oxidation products, either normal or abnormal, either alone or with the presence of albumin in the urine, should always be regarded as a danger signal and be removed, if possible, before it is too late.

The second cause of degenerative changes in the renal epithelial cells is found in the putrefactive fermentation so frequently met with in the alimentary canal. This condition results in the formation of toxic products, either formed in the alimentary canal or produced within the system. They may be in their formation either oxidation reduction products or isomeric forms of the proteid elements that are toxic in nature. The latter view is the one that appears to be the most thoroughly in harmony with the laws of chemistry, as these processes are at present enunciated. In either case they are toxic, and have a tendency to destroy the life activity of the protoplasmic structures that are called upon to oxidize or still further, isomerically, transform these proteid elements into the excretory products found in the urine. As in many instances, they are simply isomeric forms of the proteid molecule, it becomes a very difficult matter to chemically detect and isolate those which are toxic in their nature from those that are inert, yet in many instances this has been accomplished. In all instances the toxicity of these substances can be determined by physiological experimentation. With many of these compounds this has already been accomplished, but there are many more to be thus analyzed.

When this condition of putrefactive fermentation of the proteids is taking place in the alimentary canal, there is formed a substance that has received the name indican or indoxyl potassium sulphate. This substance, by virtue of its combination with the inorganic substance potash, obeys the law common to almost all inorganic substances, and is readily absorbed as such from the alimentary canal, and escapes under its own form from the system through the renal glands, and appears in the urine. When this occurs its presence is easily detected in the urine, and another danger signal is set in this excretory fluid by which the physician is warned of impending danger to the renal structures.

The third and most intense cause of degeneration of the renal cells is the presence of microorganisms acting either directly or indirectly. Directly when they are acting within the system, upon the proteid structures which go to make up the integral parts of the body; indirectly when they are acting upon the proteid elements contained in the food products while within the alimentary canal. In either instance they may produce toxic products as already described oxidation reduction products, or isomeric proteid elements. In the one instance they are produced within the system, in the other within the alimentary canal to be absorbed therefrom into the circulation. In either case the nutrition in general is impaired, and the kidneys are called upon to perform an excessive amount and abnormal kind of work, hence their degeneration. It is further highly probable, if not absolutely proved in all instances, that different kinds of bacteria produce different kinds of toxic substances, either of the oxidation reduction type or of the isomeric proteid form. From the almost uniform absence of oxidation reduction products in the blood and lymph, and their presence in all the excretions of the body, it seems highly probable that they are formed by a process of oxidation in the excretory cells of the glandular organs. From this fact it is highly probable that the toxic products within the system are more likely to be of the isomeric proteid form, hence the greater difficulty of detecting and isolating them. Some observers, as Adami of Montreal, go so far as to affirm that all the different forms of renal lesions are the result of the direct action of the bacteria and their products upon the renal structures, and that the bacterial action is entirely within the system[1]. In many instances this is unquestionably true. On the other hand, however, from all the evidence at our command, it is more probable that, in a vast majority of cases, the bacterial action, when it acts as an exciting factor in producing these renal lesions, is brought about in the alimentary canal, and not within the system. It is the bacteria acting upon the proteid elements of the foodstuffs in the alimentary canal that excites all the putrefactive changes already described, and thus indirectly, and not directly, the bacteria act as the etiological factors. Insisting, as Adami does, that the bacteria are in all cases the direct and only etiological factor in producing these renal lesions, seems like carrying the bacterial side a little too far; but when looked upon in the broader sense, and as capable of acting indirectly or secondarily, as already described, then the bacterial explanation will unquestionably account for a very large percentage, if not for all the renal lesions of the parenchymatous type.

Regarding the conditions that interfere with the normal nutrition, it is apparent to the simplest observer that the very conditions that tend to overwork the kidneys tend at the same time to interrupt or lower the nutritive activity of the renal glands, and these are the conditions that disturb nutrition. Viewed in this double light, the preventive and direct treatment of these renal lesions is more scientific and practical.

Next to be considered is the development of the interstitial forms, and here the etiological explanation is still more complicated. At the same time it is equally as clear if the physiological laws governing the animal economy are closely followed. The interstitial form is largely dependent upon the three conditions already outlined as causing the parenchymatous changes. In attempting to explain the development of new connective tissue at any point in the body, the vascular as well as the chemical law governing nutrition must always be kept in mind; namely, that all increase or decrease in nutritive activity is always and at all times dependent upon an augmentation or a diminution in the nutritive supply (namely, the blood) brought to the part by its vascular supply. This refers to the quantity as well as quality. This statement refers chiefly to the condition of the arterial capillaries. If this set of vessels is expanded and the current slow, there is augmented nutrition, provided the tissues are in a condition to appropriate to its own use the proteid elements of the blood. If for any reason the congestion is carried to too high a degree, a condition bordering on stasis is developed. Then nutrition is arrested. On the other hand, if the arterial capillaries are too highly contracted, and the blood flows too rapidly through the part, nutrition is decreased or arrested. Thus over-expansion and over-contraction may both arrest nutrition. The latter is more commonly the cause of arrested nutrition and more intense in its action.

In the parenchymatous groups of cases, where the cells enlarge rapidly and tend to compress the intertubular plexus of vessels in the kidneys, there is a decided decrease in the nutritive pabulum distributed, both to the interstitial as well as to the epithelial structures, the same as if the vessels *per se* had been unduly contracted. Therefore, as a natural sequence of this compression of the vascular supply, the intertubular connective tissue has a tendency to undergo atrophic changes, although to to the casual observer it often appears to be increased in quantity in consequence of an infiltration of the perivascular spaces with an undue amount of water. This œdematous condition of the intertubular connective tissue is produced, as dropsy is, in all parts of the body, by the walls of the blood vessels first losing their nutritive tone and then their function. When this occurs the capillary blood vessels discharge the watery constituents of the blood into the perivascular spaces more rapidly than the lymphatics can remove it therefrom. The inherent fibers, however, atrophy, and the perivascular spaces are filled with water, forming a solid œdema. When this condition is closely analyzed under the microscope, it is easily apparent to any microscopist that there is no actual increase in the tissues. On the other hand, if the retrograde changes in the epithelial cells are more gradual, accompanied by a desquamation of the cells, it may be associated with the opposite condition of the intertubular vascular supply, and in this manner a true development of connective tissue is produced. This decrease in pressure upon the plexus of blood vessels between the tubules causes an expansion of the capillaries, and is followed by an augmentation of the vascular supply, thus distributing more than the normal amount of nutritive pabulum to the intertubular connective tissue. The result of this rapid but progressive desquamation of the epithelial cells ultimately leaves the tubules, as it were, denuded of all of their epithelial cells and the vessels unsupported from this side. As a natural sequence, there results a greatly augmented flow of blood through the connective-tissue structures, and this, in turn, is followed by a decided increase in the connective tissue. Of course, there is only a limited number of tubules thus affected at a time, hence this type of lesion is apt to be progressive and to have frequent exacerbations and remissions.

There are other methods by which an augmentation in the vascular supply to the renal glands, and to the intertubular tissue in particular, can be brought about with the development of new connective-tissue between the tubules. It is quite within the range of possibility that the toxic products in their transit through the walls of the blood vessels on their way from the blood stream to the protoplasm of the excretory cells are brought into direct contact with the peripheral nerve endings that govern the contraction and expansion of these capillary vessels. When this occurs some of the toxic products paralyze the nerve endings distributed to these vessels, and the force of the blood stream from the arterial system causes an over-expansion of the arterial capillaries between the tubules, and a hypernutritive activity ensues with the production of new connective tissue. Similar changes can be brought about by what is known as the reflex action of the nervous system. The toxic products in passing through from the blood stream to the epithelial cells are as before brought into contact with the peripheral nerve-endings, but instead of acting as paralyzing agents to the nerve-endings they now act as irritants. This peripheral irritation is carried up to the cerebrospinal centers controlling the vascular system by the centripetal nerves, from which centers impulses are sent out to the vascular system through the centrifugal nerves, with the final result that the arterial system at large contracts, but with a corresponding low tension in the splenic arcade, thus causing a pronounced and continuous dilatation of the capillary blood vessels between the tubules. Thus a continuous augmentation of the renal circulation produces progressive formation of new connective-tissue. In still other instances the toxic products act directly upon the cerebrospinal centers that control the vascular system, and in this manner produce very nearly the same vascular changes in the renal circulation with augmented nutrition and the formation of new connective-tissue between the tubules. In still other instances the toxic products produce their peripheral and primary irritation at some remote part of the body, so far as the kidneys are concerned, as, for instance, along the line of the alimentary canal. From this point they act reflexly through the central nervous system, causing the same general high tension, with corresponding low tension in the splenic arcade, followed by augmentation in the vascular and nutritive activity in the kidneys, as already described. All of these methods are in full accord with the well-known physiological laws that govern nutrition. They simply augment the physiological into a pathological condition. It matters little which one of these explanations is accepted, they one and all tend to bring about the same condition, so far as the vascular supply and the production of new connective-tissue in the kidney are concerned. It is unquestionably true, however, that at different times in the same case and in different cases one and all of these laws come into play in the production of the varied types of renal lesions that are found at the necropsy. It clearly explains the parenchymatous, the interstitial, and the diffuse formations, depending upon which etiological factor predominates. All these explanations have been made possible not by clinical observation, but through years of careful research and observation carried on in our physiological and pathological laboratories. Without this kind of work medicine would be no further advanced to-day than it was a quarter or half a century ago. So, in the future all true advance in the science of medicine and its practical application for the benefit of suffering humanity must come from this same source, hence the great and increasing demand for larger laboratory facilities and workers in this line in all public institutions, until chemistry, physiology, pathology, and clinical therapeutics are brought into close and continuous touch. This fully accomplished, medicine will advance more rapidly than ever before in its history. When chemistry, physiology, and pathology are brought into full relation with the clinical side of medicine, it is perfectly marvelous what can be accomplished. The healthy and the diseased can be viewed like pictures—the oft obscure and difficult problem becomes clear and easy of elucidation.

With this full understanding of the production of the various forms of renal lesions, their treatment is best considered under two common headings; first, that of prevention, and, second, that which is applicable after positive development of the renal lesion.

Knowing that the parenchymatous lesions, or those involving the epithelial structures alone, are largely due to over-eating and drinking, but especially the former, great care should be exercised in the regulation of the diet. Knowing also that putrefactive changes in the proteids in their passage through the alimentary canal are frequently responsible for this class of renal lesions, this tendency to putrefactive fermentation should be carefully corrected. The damaging effects of the bacteria, either acting directly or indirectly, must not be neglected in the preventive treatment. In health, as well as in disease, the quantity as well as the quality of the food taken must always be kept well within the oxygenating capacity of the animal economy, if overwork and a faulty nutrition of the renal glands is to be avoided. If putrefactive fermentation of the proteid constituents of the foodstuffs in the alimentary canal is to be prevented, not only must the quantity of food taken be limited, but the quality also must be well guarded. All substances that have a tendency to undergo saccharine fermentation, or that produce undue irritation to the intestinal tract, must be rigidly excluded from the dietary. While simple fermentation of the saccharine elements alone in the alimentary canal produce very little harm, this fermentation in itself has a tendency to cause intestinal irritation, and is soon followed by a pronounced putrefactive fermentation of the proteid elements contained in the alimentary canal. This putrefactive fermentation is quickly evidenced in the urine by varying quantities of indican. On the other hand, the incomplete oxidation of the proteids is as quickly told by an excessive amount of uric acid in the urine. Therefore, uric acid in the urine in excess of the normal quantity is proof positive of either over-feeding and an imperfect oxidation of the proteid elements, or a defective oxidation from an incomplete oxygen supply to the system. Indican in the urine is proof positive of a putrefactive fermentation of the proteids in the intestinal canal, which is always associated with the formation of toxic products in the intestinal tract and the absorption therefrom into the system of varying kinds and amounts of toxic elements, or with these conditions the toxic elements may be produced within the system as the result of an abormal isomeric transformation of the proteid elements in their transit through the body. No matter how little the toxic product or where it is produced, its circulation through the system always disturbs nutrition and overtaxes the excretory functions of all the glandular organs of the body, and especially the renal glands. Too much stress cannot be laid upon the significance of these two substances in the urine, nor upon the importance of recognizing their presence in the urine early, and also the necessity of removing the conditions that make possible their presence in the urine, if prevention or cure of renal lesions is to be successfully accomplished. Both of these conditions are positive indicators of a deteriorated state of the animal economy, and one which tends to lower the general nutritive activity of the system and invite bacterial invasion, for without a suitable medium the germs cannot thrive in the economy, nor produce their damaging effects. Therefore, it becomes clear that, to prevent an invasion of the system by bacteria whose poison will eventually damage the renal structures, the two conditions just enumerated must be prevented. This accomplished, the possibility of developing renal lesions, involving chiefly the epithelial structures as the result of a bacterial invasion, is reduced to the minimum. With this understanding of the subject, it is difficult to see how operative interference can be of avail in preventing this class of lesions.

When it comes to the prevention of the multiplicity of conditions that influence the circulatory apparatus, and thus cause a modification in the nutritive activity in the intertubular structures of the renal glands, it is by no means as simple an undertaking as is the removal of the conditions that enter into the production of the parenchymatous forms of renal degeneration. Nevertheless, the removal of all the etiological factors that enter into the production of the parenchymatous or epithelial group of lesions will, in itself, produce the highest type of nutritive activity throughout the system, and thus materially aid in preventing disturbances in the circulatory mechanism, which will be liable to produce pathological changes in the intertubular portions of the kidneys. In this manner a more uniform nutritive condition of the whole system is maintained, and the normal integrity of the renal structures, as a whole, is sustained. This accomplished, the kidney tissue, both tubular and intertubular, and, in this instance, particularly the latter, is safeguarded against the development of new connective-tissue in the intertubular portions, and thus the interstitial forms of renal lesions are prevented. Therefore, that which at first seemed almost impossible to attain has been in a large measure secured.

What has been said in regard to the prevention of the epithelial and interstitial changes singly, applies with equal force to the prevention of the combination of the two when developed together, as occurs in that set of lesions known by the name of a diffuse lesion of the renal structures. The predominance of the one or the other type of lesion or the combination of the two in the same kidney is governed by the kind and amount of the toxic products that are brought to bear upon the renal cells or upon the nervous mechanism that controls the circulatory and nutritive functions of the renal glands. Therefore, it becomes clearly apparent that all forms of renal lesions are dependent primarily, and in a very large measure, upon what the individual eats and drinks. It is further equally as certain that all the toxic elements that act as the exciting factors in determining the different types of kidney disease commonly classed as "Bright's disease" are derived from the imperfect utilization of the proteid elements contained in the food products or in the structures of the body, more probably the former. It should always be remembered that the proteid elements come from the vegetable kingdom as well as from the animal, and, so far as is at present known, the one class of proteids is no more likely in itself than is the other to be isomerically, or by a process of oxidation reduction, converted into a toxic form. The vegetable class, however, is the more difficult of digestion, and is combined with other fermenting substances, which tend to excite intestinal irritation and putrefactive fermentation of the food products while passing through the alimentary canal, consequently in this secondary manner the vegetable class is more likely to cause trouble than the animal.

Aside from what we eat and drink, lack of exercise in the open air, sedentary habits, unhygienic surroundings, over-work, both mental and physical, and especially the former, must never be lost sight of as factors that enter into the possibilities of a perfect or imperfect digestion, circulation, and utilization of the food products taken into the system. Therefore, all these conditions must receive due consideration and be corrected, when necessary, if the best utilization of the food elements is to be secured, nutrition normally sustained, and the development of these renal lesions prevented.

Here, again, we fail to see how operative interference can be of much avail in preventing the development of these complex lesions.

When it comes to the treatment of the actually-existing renal lesions, as evidenced by the profound changes in the oxidation products found in the excreta, particularly in the urine, and which reach their height in the form of albumin, sugar, casts, etc., a still more arduous undertaking confronts the therapeutist. All that has been said in reference to the prevention of these lesions applies with even greater force to the more difficult task of removing the damage already done to the renal structures, and bringing them to such a nutritive condition that they can again perform their function normally. While it is well-known to all that when the renal gland has become decidedly pathological in its composition, and especially is this so in connection with the intertubular tissue or the interstitial forms, it is not possible to restore the organ to its former perfect histological condition, it can in many instances be restored to such an extent that it will, for many years, perform perfectly its full function. These cases viewed with the single eye of the histologist or pathologist, can never be cured. On the other hand, if to this observation there is added the eye of the well-trained physiologist and clinician in the analysis of these cases, and especially that of the well-trained laboratory worker, the cure of these lesions, physicologically speaking, is known to be both possible and highly probable. It is very essential, however, that the existing lesion be recognized, and the special type accurately diagnosticated early in its development, if even this physiological cure is to be effected. If it is not discovered until profound changes have been wrought in the epithelial structures or in the intertubular tissue, or in both, the possibility of recovery is reduced to the lowest ebb, but when the lesion is recognized early and suitable treatment is at once instituted, recovery is the rule. This assertion may at first be considered doubtful, but when these cases are carefully analyzed and treated in the light of the recent advances that have been made in physiology and therapeutics based thereon, it will be found true.

In the face of all this, and with this very complex chemico-pathological condition before us, we are confronted by the surgeons with the proposition that operative interference is the best method for treating chronic "Bright's disease." This assertion appears to have been brought out by the apparently good results, in some instances, that have followed splitting the renal capsule as advocated by Harrison,[2] and the still more radical operation of decapsulating the kidney as advanced by Edebohls,[3] the latter claiming that decapsulation brings about circulatory changes that are essential to a cure of "Bright's disease." Looking back upon the very complex nature of the etiology and pathology of "Bright's disease," it is a very difficult matter to comprehend how the operations advocated can remove a single one, to say nothing of the many intricate etiological factors entering into this complex problem. The same may be said regarding the pathological changes, which are equally as intricate as the etiology. The well-trained therapeutist is often able, as we have already seen, to remove many, if not all, of the etiological factors. Further than this, he can remove many, if not all, of the more prominent symptoms in "Bright's disease," and for a time, at least, cause the renal glands fully to perform their functions normally. It should always be remembered in this connection, however, that, owing to the inherent oscillatory nature of this class of diseases, such results are not infrequent. Therefore, such satisfactory results following any plan of treatment, should not lead at once to the conclusion that a universal cure has been discovered. Every one who thoroughly comprehends the very complex nature of the etiology and pathology of this class of lesions is fully aware that there are great fluctuations in the symptoms and in the course of the disease. There are often frequent exacerbations and remissions. During the the remission the case, from a physiological standpoint, can be spoken of as cured, at the same time there will always remain a certain amount of histological damage to the renal structures, as already described. So long as the etiological factors that originally excited the disturbance in the functions of the renal glands, and thus cause the familiar symptoms of "Bright's disease," can be held in abeyance the remission will continue. This may be for years, months, weeks, or only for a few days. In many instances, with scientifically directed therapeutics, based on advanced chemico-physiology and pathology, it has been my privilege to see it continue for years. In such instances a cure has practically been effected, yet a relapse may develop at any time, as illustrated in the following case: I saw the case some six years ago, in consultation. The patient, a man of fifty-five or fifty-six years of age, had been ill for more than three months. For several weeks before my first visit he had not been able to lie down, on account of a general œdema and distressing dyspnœa. These were the two most prominent symptoms. The urine contained albumin and casts, and a small amount of urea, and an excess of uric acid. After several months of careful dietetic and therapeutic treatment, all the glands, and especially the renal, performed their functions again, normally. A cure was practically effected. In June of 1901, or five years later, as the result of gross errors in diet,symptoms of active renal diseases were re-developed. For thirty-six hours the patient was comatose, the urine heavily loaded with albumin, casts, etc. Again, by a scientifically-arranged dietetic and therapeutic regimen, a disappearance of all the symptoms was brought about. And, again, he was, so to speak, cured, so much so, that in October of the same year he passed two of the large life insurance examining boards in this city, and was rated by them as an "A No. 1" risk. Ten days later, however, following a big dinner, another exacerbation occurred. Since then the urine has been normal, owing to a careful plan of dieting and suitable medication. This is only one of a large number of cases that might be recited. Had such a patient been operated on in any of the exacerbations, and survived the operation with a similar disappearance of the symptoms, the results might have been attributed to the operation.* This well-known fluctuating habit, in many forms of "Bright's disease," must always be borne in mind in analyzing results of treatment. Whatever line of treatment is adopted, it should be directed toward the removal of the

---

*Since reading this paper a case previously operated upon has come under my observation. First the diagnosis was stone in the pelvis of the kidney with nephritis. Failing to find the stone, the patient was informed that he had unilateral "Bright's disease," and that the operation which he had undergone would cure him.

He came to my office some six months after the operation and said that all his symptoms had returned the same as before the operation, that he was both disappointed and discouraged.

Examination of the urine showed albumin and indican etiological factors as well as toward the removal of symptoms. Operative interference does not remove any of the etiological factors, unless it be the loss of contractility and expansibility of the renal gland taken as a whole, which we found, in studying the functions of the kidneys, was essential to a perfect performance of the functions of the renal glands. If operative interference can be shown to accomplish this, and thus uniformally improve the physiological activity of the renal circulation, then it removes one of the many etiological factors that enter into the production of this complex problem designated "Bright's disease."

A somewhat similar improvement in the renal circulation, with a diminution or disappearance of the albumin and casts from the urine, is effected, in some instances, by the use of nitroglycerin. This drug causes a general expansion of the arterial system, with a corresponding decrease in the renal engorgement, and thus brings about a freer and more physiological flow of blood through the pathological renal structures. When this occurs, it is often followed by an active decrease or complete disappearance of all the abnormal urinary symptoms. These results, tended at one time, to the belief that nitroglycerin would cure "Bright's disease," but, like many other plans of treatment advocated from time to time, it failed to come up to the full requirement of first removing all the etiological factors, consequently it, like many other single remedial agents, failed. In like manner, it seems highly improbable that incision into the capsule, or decapsulation of the renal organs, will fulfill all the requirements that are essential to hold in abeyance all the etiological factors that are increasing the work of the renal glands, and at the same time decreasing the nutrition of these organs, and that are thus keeping in motion the condition that we are accustomed to diagnosticate under the generic term "Bright's disease." Hence, operative interference, like any other single and limited method of treatment, is liable to be disappointing in most instances.

The successful treatment of this class of diseases calls for a much wider range of therapeutic skill than simple operative interference.

In treating the fully-acquired lesions, out-of-door exercise must be insisted upon with as much precision as the use of medicines. Exercise must not be taken to the extent of producing exhaustion, but in sufficient amounts to increase the oxygenating capacity of the system, so that it will be enabled more perfectly to oxidize the proteid constituents. The clothing must be such that it will prevent undue chilling of the surface of the body from the sudden changes in the atmospheric temperature. In fact, the best results are obtained where the surface of the body is kept in a gentle perspiration at all times. All insanitary surroundings must be removed. Overwork of the muscular and nervous system, and especially the latter, must be avoided. All mental worry, or anything that tends to disturb digestion, is contraindicated, and must be controlled in some manner. The chief and all-important treatment, however, consists in the perfect management of the diet in accord with our advanced knowledge as to its composition and utilization by the system. Here, as in all other diseased conditions, as well as in health the well-regulated mixed diet is the ideal one to institute.

The recital of a few general priniciples in relation to diet is essential to a full comprehension of this all-important subject. Four general laws underly the whole subject. First, for the best working of the physiological economy it is necessary to take a certain amount and quality of the so-called inorganic elements, all of which act simply by their mechanical presence while they are within the system. Second, it is necessary to take the requisite amount and quality of simple heat-producing substances, such as starch, sugar, and fat, compounds that are directly oxidized into carbon dioxide and water with the production of heat. Third, the introduction of the requisite amount and quality of the proteid elements or the true and only tissue-building substances; and, fourth, there must be supplied to the system the necessary amount of that complex substance in which the iron and phosphorous atom is combined with a proteid, known as nucleoalbumin, and out of which the hæmaglobin for the blood and the lecithin for the nerve tissue is formed by oxidation reduction.

The milk diet which has been so long extolled in the dietetic management of all renal affections, is largely deficient in this essential nucleoalbumin compound; hence, it cannot be considered an ideal diet in any class of lesions in which a progressive anæmia is one of the essential features, as is the case in connection with all renal lesions. In like manner, meats of all kinds, while they are, like milk, the best of all food substances for supplying an available form of proteid for tissue-building, are also deficient in this hæmoglobin-forming compound, nucleoalbumin; consequently, they are not ideal in their nature. It must always be remembered, however, in this connection that beef proteid is the most easily digested, absorbed, and assimilated of all the known proteids. This is true both of the animal as well as of the vegetable class. Eggs and milk stand next in the order enumerated, while the proteids derived from the vegetable classes are the most difficult of all to digest. All of the animal class, as well as those enumerated, are defective in the amount of the hæmoglobin-forming element, nucleoalbumin, but the amount contained in the animal kingdom, like the associated proteid, is much more available than the same substances which are often found more abundantly in the vegetable kingdom.

Turning now to the vegetable kingdom, it, like the animal class, is found to be abundantly supplied with proteid elements and to contain a superabundance of the hæmoglobin-forming element, nucleoalbumin, as compared with the animal class. While both the proteid and nucleoalbumin is less available than that found in the opposite kingdom, it can be made to readily supply the deficiency of the animal class. At the same time it must always be remembered that, when resorting to the vegetable kingdom to supply this much-needed nucleoalbumin, foods are being introduced into the alimentary canal that contain an excess of the starchy and saccharine compounds, and that these hydrocarbon compounds, by virtue of the ease with which they are digested and absorbed, are very apt to overtax an already defective oxygenating capacity of the system, and thus add, as it were, fuel to the fire by still further retarding the oxidation of the proteid elements, which even normally are more difficult of reduction. Further than this, many, if not all, substances derived from the vegetable kingdom are irritating to the alimentary canal, and easily undergo saccharine fermentation, while, as we have already

---

in considerable quantities. There was a slight decrease in the elimination of urea and a large excess of uric acid. Microscopically, the urine showed uric acid in abundance, large numbers of red blood cells, hyaline and granular casts. Evidently an acute exacerbation in the course of a chronic "Bright's disease." Under appropriate dietetic and medicinal treatment the symptoms are rapidly disappearing, and again an apparent cure is being effected, as illustrated by the cases recorded in the body of the paper. This case demonstrates conclusively that operation does not permanently cure "Bright's disease" found, their contained proteids are very difficult of digestion compared with those derived from the animal kingdom. In fact, the proteids of vegetables often pass through the alimentary canal untransformed into a peptone, which is the only isomeric form of the proteid molecule, at present known to be taken up from the chyme by the epithelial cells lining the intestinal tract, to be discharged therefrom, in various other forms, into the bloodvessels, thus forming the various albuminous constitutents that are found in the blood and tissues of the body.

This being true in health, it is so, to a much higher degree, in diseased conditions. Therefore, we have it conclusively established that neither the animal nor the vegetable class of foodstuffs alone is wholly available in the dietetic management throughout the whole course of this or any other class of diseased processes.

This being an established fact, the best results are attained in the management of this class of cases, as in all other forms of disease, by the use of a well-regulated mixed diet as soon as it can be digested and assimilated.

A good example and illustration of this principle occurred in a case that I saw in consultation last winter. It was that of a young woman pregnant for the first time. She was in the ninth month of her pregnancy, but just how far along could not be determined. The week before Christmas the urine was examined and found to be practically normal. During the holiday festivities she indulged in many errors in diet. On the sixth or seventh day after New Year's day, the attending physician discovered albumin and casts in the urine, and recognized at once the critical nature of the situation. He had the patient go to bed, and placed her on a milk diet. When I saw the patient, which was on the tenth of the month, the urine was heavily loaded with albumin, the elimination of urea was reduced to about one-half the normal quantity. The urine also contained hyaline and granular casts, indican, and uric acid in large amounts. The patient was decidedly toxic (uræmic) and on the border-line of eclampsia. At my suggestion, the bowels were acted upon freely by compound cathartic pills, the patient was placed on a well-regulated mixed diet, and allowed to get up and take regular exercise. During the following forty-eight hours the excretion of urea progressively increased until it rose above the maximum. At the same time the indican and uric acid decreased. The albumin and casts, however, remained practically unchanged in the urine. All the toxic symptoms disappeared, and three days later the patient appeared to be in a fairly normal condition, aside from the albumin and casts. The symptoms having assumed a less serious aspect, no effort was made to terminate the labor. Four days after the patient had been placed on the mixed diet, with attention to the digestive and hepatic functions, Nature terminated the pregnancy in natural labor, the child being born without an untoward symptom. There were no after-symptoms, and on the day after delivery the mixed diet was resumed. The elimination of urea was kept well up to the normal standard, the indican, uric acid, albumin, and casts gradually disappeared from the urine, and the patient made a perfect recovery. The baby was strong and healthy.

This is only one out of many cases that could be cited showing the good effects of a well-regulated mixed diet, assisted by scientifically-applied therapeutics.

A well-regulated mixed diet is one that is composed of both the vegetable and animal class, but one in which the latter largely predominates. Where Nature unaided cannot digest such a diet, she often can be assisted by the judicious administration of medicinal agents. When, for any reason, the system has degenerated to the point that it cannot be made to utilize a well-regulated mixed diet, the prognosis is bad, and death will ensue sooner or later, all of which is fully demonstrated by clinical experience.

Many observers lay great stress upon the exclusion of the red meats and advocate the use of the white meats only. Where this is the case it is quite apparent that the fullest knowledge in relation to the composition of the foodstuffs and the physiology of digestion and the utilization of the different elements contained in the two kingdoms is not brought to bear as it should be upon this all-important question. Of the two, the red meats are to be preferred.

Careful experimentation upon the human subject has demonstrated conclusively that the proteid of beefsteak or red meat is the most easily digested, assimilated, and oxidized of all the proteids, the loss being only 2 per cent. Eggs rank next, and milk comes third on the list, and so on down through the list of food products until oatmeal is reached, which is the most indigestible of all known substances, for with oatmeal there is a loss of 80 per cent. as compared with the amount ingested. It should further be remembered that no matter what the original form of proteid is, it must in every instance be reduced from the multiple to the single molecular state, and from this condition be transformed into that isomeric form known as a peptone before it can be taken up by the epithelial cells. Therefore, when the chemistry of digestion and absorption is under consideration the investigator has to calculate only with that state of the proteid molecule known as a peptone, because all proteids must be reduced to a peptone before they can be absorbed. So far as is known to the chemist, it is neither red nor white, but in all instances of the same isomeric form of construction, having lost its former identity in the digestive process. Consequently, the real question at issue is what form of proteid can be most easily transformed into a peptone with the least expenditure of digestive energy. This has been settled in the order above named by the experiments of König,[4] Rubner[5], Hofmann,[6] Strümpell,[7] Prausnitz,[8] Meyer,[9] Monk,[10] Atwater,[11] Chitenden Cummins,[12] and others. In the vegetable class, wheat ranks first, but is still considerably behind the animal class.

With the foregoing facts before us, what reasonable excuse can be offered for using food products that have in their construction a tendency to irritate and overtax an already enfeebled digestive and assimilative state of the system. Why not use instead those that are the most easily peptonized and absorbed. It appears to the author of this paper that the disregard of these fundamental principles resulting from a false interpretation of facts by many teachers, is the one great reason why so many failures have been recorded in the management of these renal lesions. On the other hand, it explains fully why such phenomenal results are obtained by those who adhere more closely to the known laws of chemistry and physiology and govern the work of the animal economy with such absolute accuracy.

Medication, so-called, as formerly used, and as it is still employed in many instances at the present time, simply adds fuel to the fire and absolutely prevents Nature from accomplishing what she might otherwise do, and thus prevents recovery. On the other hand, when these exact chemical laws are fully compehended and so-called medication applied in full accord with these phenomena and principles, Nature is greatly aided in her efforts,not only to prevent the development, but in bringing about a physiological cure of these diseases. The treatment should be directed not so much to the kidneys as toward removing the etiological factors that enter into the production of these lesions. When this plan is followed, even after the full development of the disease, it will in many instances assist Nature to remove the causative factors and, as far as is possible, repair fully the local damage, so that the result is almost miraculous in its completeness. When this plan of scientific dietetics and therapeutics is more universally applied in the treatment of this class of lesions there will, in my opinion, be few cases calling for operative interference.

The conclusions to be drawn from this study are:

1. To analyze thoroughly the results of treatment in "Bright's Disease" one must have a clear conception of the histology and physiological functions of the kidneys.
2. Its complex pathology must be clearly understood.
3. All the etiological factors must given full consideration.
4. The etiological factors are numerous and very complicated in their action.
5. Only *one*, if any, of these can be reached by surgical interference.
6. Most of the etiological factors can be modified or removed by well-directed rational dietetics and therapeutics.
7. Histologically speaking, "Bright's disease" can never be cured.
8. Physiologically speaking, the etiological factors can be modified, and often removed, the symptoms held in abeyance, while the renal glands perform their functions normally.
9. "Bright's disease" is by nature an oscillatory malady, accompanied by frequent remissions and exacerbations.
10. *Remissions must not be mistaken for cures.*
11. Rational dietetics and therapeutics offer the largest possibility for a complete physiological cure.
12. A well-regulated mixed diet, especially if composed largely of the animal class, when it can be tolerated, yields the best results.
13. All therapeutics to be rational must be directed not at the pathological lesion *per se*, but toward establishing a more perfect digestion and metabolism and a decrease in the work imposed upon the renal glands.

"THE STRATHMORE," BROADWAY AND FIFTY-SECOND STREET

TUBERCULOSIS OF THE URINARY TRACT.*

BY P. NEWMARK, M.D.,
LOS ANGELES, CAL.

THE physician, whose duty it is to examine a patient for disease of the urinary tract, finds himself in a somewhat peculiar position which differs from that in which one is usually placed in examination for other troubles. Abundant and different as are our diagnostic aids, perfect as are our newer instruments, one must first answer the question whether he may make use of these technical helps. Even though one proceed immediately to the use of the laryngoscopic mirror in laryngeal troubles; although he subject a diseased eye at first sight to a thorough and extensive examination by the various illuminating apparatuses, yet the disease of the urinary tract always imposes a certain hindrance in the use of diagnostic aids which is not to be underestimated.

The sound, catheter, and cystoscope may, in many cases, quickly and surely satisfy the diagnostic need, yet one must at first, and occasionally through the entire course of the disease, abstain from their use. The application of these methods constitutes an operative procedure from which a patient may suffer considerable damage, even though the greatest care and most rigid asepsis has been observed in their application.

If what has been said applies to disease of the urinary tract in general, it is more especially applicable to the *tuberculous* diseases of the same.

As the brief time allowed to me in this symposium permits only a hurried survey of the advanced data in the knowledge of these diseases, I will confine my remarks to the discussion of tuberculosis in two organs—the bladder and the kidney.

With regard to the *etiology* of these diseases, we must acknowledge that the theories of the various authors concerning the development and spread of the tuberculosis of the genitourinary tract differ. Some assume that the affection desends from the kidney to the genital organs, others while admitting the possibility of this origin, hold that the process ascends from the genital organs to the urinary tract. Of course, the essential etiological factor in tuberculosis of the bladder, as in tuberculosis of other organs, is the tubercle bacillus.

The route through which the bacillus reaches the bladder might be manifold. The larger percentage of cases are undoubtedly induced by the urine carrying the bacillus from the kidney or ureter and the bladder becoming involved by mural implantation. Probably next in order of frequency is the extension from the ureter directly to the ureteral orifices and the bladder. Less commonly infection might occur from tuberculosis of the prostate. The involvement of the bladder by extension from the seminal vesicle is possible, but undoubtedly rare, and probably least common of all is infection of the bladder from the blood stream.

As no age is exempt from the disease, we should not place any diagnostic importance upon the age of the individual in any given case. More important are family susceptibility or antecedent affections of the urinary tract, especially gonorrhœa.

In a paper read before the "Verein für innere Medizin of Berlin," Casper[1] mentioned the fact that of his thirty-five cases of tuberculosis of the bladder, twelve had had gonorrhœa, and he recommends a particularly thorough treatment of these cases, as a previous gonorrhœal cystitis not infrequently prepares the soil for tubercular infection.

As to symptomatology and diagnosis of tuberculosis of the bladder. I would state that while tuberculosis in most organs is accompanied by a more or less conclusive clinical picture, this applies least of all to the tuberculosis of the urinary organs. There are several very significant symptoms indicative of tubercular affection of the bladder, but not always such as that they could not be mistaken for some other disease of the bladder, and, furthermore, we often encounter cases of tuberculosis of the bladder without those characteristic symptoms being present. On this account it is extremely essential that in considering the diagnosis of such cases one idea should always be borne in mind. There is not one method or one significant clinical feature by means of which a man can with ease and positiveness make a diagnosis for or against tuberculosis in all these cases. It is only by bringing into play all the factors that the laboratory and clinical observation can control that a man can say in very many disputed cases of the urinary tract that a disease is or is not of a tubercular nature.

---

*Read at the twenty-ninth semi-annual session of the Southern California Medical Society at Idyllwild, Cal.

Frequent desire to urinate, with painful micturition, and the pathological condition of the urine, are the chief symptoms met with in such cases. The first thing to attract the patient's attention is his frequent desire to urinate. Urination becomes more frequent as the disease advances, and is soon associated with pain, which is usually experienced about the middle of the penis. This symptom is very significant of tubercle, and differs from that which pertains in calculus, where the pain is felt at the meatus; and whereas in tubercular disease of the bladder the pain is present before, during and after urination, it is not so much aggravated after emptying the bladder as is the case in stone.

In the later stages of the disease the violent contractions to which the walls of the bladder are subjected during the course of the disease, and the products of the chronic inflammatory process lead, as a rule, to great thickening and progressive contraction of the lumen of the organ, so that the capacity of the bladder in extreme cases hardly exceeds a tablespoonful. This condition is always associated with an urgent and frequent desire for micturition.

The urine exhibits the same appearance and contains the same morphological constituents as in cases of chronic catarrh of the bladder, and presents, in addition, two very characteristic features—hæmaturia and tubercle bacilli.

Hæmaturia is frequently a prodromal symptom in vesical tuberculosis, occurring only at intervals and merely in quantities sufficient to impart a reddish tinge to the urine. Profuse hemorrhage following micturition usually implies ulceration of the bladder.

The demonstration of the presence of tubercle bacilli in the urine, however, is the most reliable diagnostic resource in such cases. As this factor is of the utmost practical importance, I think a more detailed consideration of this point justifiable, partly because the staining and detection of tubercle bacilli in the urine sediment is somewhat difficult, partly on account of the necessity of their differentiation from other bacilli, which may at times resemble them.

In the first place, it is a well-established fact that tuberculosis of the urinary apparatus may be widespread without the investigator having been able to demonstrate the presence of bacilli in the urine, and while every general practitioner is able to demonstrate with comparative ease the presence of tubercle bacilli in tuberculous sputum, it becomes a more complicated affair to detect them in the urine.

The secret of finding tubercle bacilli in the urine lies in rapid sedimentation by the centrifuge and immediate staining. Urine which has stood sufficiently long to sediment in the ordinary conical glass commonly fails to show the organisms. However, even with the utmost care and consideration of this point, we are often unable to detect tubercle bacilli in the urine. Is this due, perhaps, to the morphologic changes the organism undergoes in the acid urine, so that we no longer recognize it? While partly due to the condition named above, the failure to find the organisms is to a greater extent due to the small number of bacilli present in the urine.

If the bacilli cannot be found, the injection of a few drops of the urine sediment into the eyes, a joint or the peritonal cavity of a rabbit will often succeed in reproducing the disease.

Regarding the differentiation of the tubercle bacilli from other bacilli, it may be stated that the only organisms which may be mistaken for tubercle bacilli are smegma bacilli. That the error is a common one can be concluded from the many cases reported in the medical literature where smegma bacilli had been mistaken for tubercle bacilli. As the smegma bacilli are very commonly present about the genitals, it has been suggested, in order to escape this error, to draw the urine by the catheter. Sondern,[2] however, who has made an exhaustive study of these conditions, has found smegma bacilli in urine drawn by catheter, and even in separately collected urine, and he has, therefore, abandoned the conclusion advocated by others, that urine obtained by catheter from the bladder contains no smegma bacilli, so that these specimens should have the same care in differential staining as those voluntarily voided.

There are, however, several points, the consideration of which will almost in every case enable us to differentiate tubercle bacilli from smegma bacilli, and these are the staining, grouping and cultivation of the bacilli found in the sediment.

As to the differential staining, we see the smegma bacilli completely decolorized by acid-alcohol, while at the same time no action on the color of tubercle bacilli. Regarding the grouping, I would say that smegma bacilli may occur in clumps or single; when in clumps the arrangement is usually an irregular one, but never in the characteristic groups of tubercle bacilli. On the other hand, tubercle bacilli found in the urinary sediments occur single at times, but in the large majority of cases in smaller or larger groups. The grouping is generally characteristic—the bacilli lie side by side, parallel, and end to end in a more or less regular arrangement.

If there should be any doubt left, it is advisable to resort to cultivation, the smegma bacilli growing much faster than tubercle bacilli.

The cystoscopic examination in cases of tuberculosis of the bladder does not offer a very characteristic picture in general, and is, as a rule, contraindicated on account of the great irritability and hyperæsthesia of the bladder, and its inability to expand. In some cases, however, it will aid in determining the starting point and extent of the disease present.

The two places in which tuberculosis of the bladder is most likely to commence are the ureteral orifices and the trigone of the bladder. The former starting point of the disease is the rule when the disease is secondary to renal tuberculosis. The trigone is usually the starting point in primary tuberculosis of the bladder, or by extension of the disease from the genital organs. In some cases, where no bacilli can be found, we may thus be enabled to clear up the diagnosis by detecting typical gray nodules, or the so-called lenticular ulcers, or to suspect the involvement of the kidneys.

The treatment of tuberculous disease of the bladder can be divided in general treatment, direct medication, and surgical procedures.

With regard to general treatment, it may be sufficient to state that dietetic, climatic, and proper hygienic surroundings play as important a part in these cases as they do when any other organ of the body is invaded by tuberculous disease

The internal use of drugs known to be antituberculous, as well as urinary antiseptics, should be commenced early and continued for a long time, especially guaiacol, beginning with three-drop doses three times daily, up to twenty drops, or the same number of grains of its carbonate, when the dose should be gradually diminished. Some authors have seen good results from the internal use of ichthyol in ten to sixty-drop doses three times a day.

Of the urinary antiseptics which are especially indicated when pus is found in the urine, I should like to mention salol, resorcin, boric acid, and methylene blue.

The local treatment of vesical tuberculosis has not proved very beneficial, unless done with the utmost care in selecting the proper cases and in using instruments that have been rendered absolutely sterile I cannot lay too much stress on the fact that a tubercular bladder is very sensitive to any instrumentation, and the handling of such cases has often recalled to my mind the experience we have in the treatment of tuberculous joints and bones, where the surgeon, by non-surgical interference, oftentimes obtains the best results. One idea should always be borne in mind—never to distend the bladder through irrigation, as over-distention invariably tends to aggravate the local condition. In consideration of this point Guyon[3] only uses instillations, preferably with corrosive sublimate, and other authors have accepted and respectively modified this treatment of vesical tuberculosis.

At first the instillations are made weak, about 1:1,000 to 5,000, twice a week, the strength of the solution and its quantity gradually increased to 50 c.c.m. If the treatment is not well borne, or is not followed very soon by improvement—lessening of pain in micturition—it is best to desist from further local medication. Nitrate of silver, so useful in the treatment of chronic vesical catarrh, has proven of no value in the treatment of tubercular cystitis. I consider this point of so much importance that whenever a case of so-called chronic vesical catarrh does not respond to a few nitrate of silver applications I am inclined to diagnose the case either as pyelitis or as tubercular disease of the bladder, unless the chronic catarrh is dependent upon the presence of some other cause, such as tumor, stone of the bladder, or hypertrophy of the prostate gland.

In some cases it becomes necessary to resort to surgical procedures in order to relieve pain, tenesmus, and the frequent desire for urination. For this purpose permanent drainage becomes necessary, either through perineal or suprapubic cystotomy. The perineal drainage seldom yields the expected relief. It requires long rest in bed. The urine cannot be prevented from escaping alongside of the drain keeping the bedding and clothing of the patient constantly wet. Therefore the suprapubic cystotomy is to be preferred, as it offers superior advantages to the operator, enabling him to deal more efficiently with the tubercular lesion. If on opening the bladder an ulcer is discovered, it can be destroyed by means of the sharp spoon, followed by the local application of iodoform to the abraded surface.

In tuberculosis of the kidney we discriminate several different forms.

From a clinical and pathological basis some authors, like Kœnig[4] of Berlin, make a division into the aucute and miliary and the chronic or caseous variety, while Senn[5] discriminates three different forms, viz., miliary tuberculosis of the kidney, caseous nephritis, and tuberculous pyelonephritis.

The first variety is nearly always bilateral, the kidney is not sufficiently enlarged by the inflammatory process to be distinctly felt by bimanual palpation and the patient succumbs in a short time to the effects of a diffuse and miliary tuberculosis.

In caseous nephritis the infection occurs in the substance of the kidney. These cases are of importance to the surgeon, because they frequently effect only one kidney and are, therefore, amenable to successful treatment.

In tuberculous pyelonephritis the disease involves the surface of the pelvis of the kidney, is frequently unilateral, and the infection is caused either by an ascending tubercular infection from the lower part of the urinary tract or by the precipitation of tubercle bacilli eliminated by the kidney upon the surface of the pelvis.

Regarding symptomatology and diagnosis, it may be stated that the most important and reliable information is furnished by a careful examination of the urine. If we find tubercular bacilli in the urine originating from the kidneys and characteristic products of kidney lesion, we are justified in making a diagnosis of renal tuberculosis. If the bacteriological examination of the urine proves negative, it does not necessarily show that the patient is not suffering from tuberculosis of the urogenital organs, and if the clinical symptoms point in this direction, inoculation experiments with the urine will frequently yield final results as to differential diagnosis between tuberculosis and other inflammatory affections of the genitourinary system.

All other clinical symptoms as pain, hæmaturia, enlargement of the kidney are very valuable in suggesting and aiding diagnosis, but are by no means pathognomonic, as renal calculus, renal tumor, stone and tumor of the bladder may present similar symptoms.

Another very valuable method in early diagnosis of renal tuberculosis is cystoscopy, to be made only when a diagnosis cannot be made by any other diagnostic means. As stated above, tuberculous affections of the urinary tract form generally contraindications for instrumentations of any kind and are, therefore, to be resorted to only in extreme cases where a final diagnosis is to be made in the interest of the patient. This visual inspection of the bladder will sometimes reveal inflammatory changes around the orifice of the ureters; it will in other cases, if there are no lesions of the bladder found, enable us to recognize the source of hæmaturia present.

Finally, by catheterizing the ureters, submitting the separated urines to microscopical examination, including staining for bacilli and if negative, by injecting a portion of each sediment into a separate guinea pig it will be possible in most cases to arrive at an early diagnosis.

The following case, which came under my observation in 1896, and which was pubished by Casper of Berlin, in whose clinic I examined the patient, may illustrate the importance and necessity of making a cystoscopic examination in some of these cases.

The patient was a woman forty-two years old, without hereditary predisposition, who for six months had complained of symptoms of vesical catarrh, to which were added pains in the right loin with a sense of abdominal tension. Varied local treatment proved unsuccessful. The urine was slightly turbid and of acid reaction, with a specific gravity of 1,018. It contained numerous pus-corpuscles, but neither blood-corpuscles nor tube casts. A small quantity of albumin also was present. In the centrifugated sediment tubercle bacilli were found. Upon cystoscopic examination the interior of the bladder appeared normal, except with a villous appearance around the orifice of the right ureter. The left ureter was readily catheterized and the urine obtained proved to be normal. The urine coming from the other suspicious looking side resembled that found in the bladder, being turbid, purulent and contained tubercle bacilli. A diagnosis was, therefore, made of tuberculosis of the right kidney with circumscribed involvement of the bladder. Accordingly, nephrectomy was performed and the patient recovered fully. The removed right kidney presented tubercles upon its surface and the caseous nodules in its parenchyma.

Thus catherization of the ureter revealed unsuspected disease of the kidney by virtue of the suspicious appearance around the ureteral orifice.

In cases where a pyelonephritis is found in an individual giving some other suggestions of urinary tuberculosis without our being able to confirm the diagnosis by the above-mentioned diagnostic means, a great deal of value is to be placed upon the injection of tuberculin for diagnostic purposes, as advocated by A. V. Koranyi.[7] This author described two such cases, in which, on account of general and local reaction following tuberculin injection—temperature of 104° and tenderness and pain in the respective kidney and ureter side—he felt justified in making a diagnosis of tuberculous disease of the kidney, and in both cases the clinical diagnosis was verified by the pathological reports.

From the foregoing remarks it is apparent that there are manifold symptoms and diagnostic means indicative of renal tuberculosis, but a probable or positive diagnosis can be made only by a careful study of the clinical history and by recourse to all diagnostic means, including a careful bacteriological examination of the urine. The earlier we recognize the condition present, the more successful will be the treatment, which is chiefly a surgical one and consists in removing the diseased organ. But before performing nephrectomy the surgeon ought to assure himself by means of the ureter cystoscope of the presence and condition of the second kidney, as "it is just as important to seek for and study the contraindications as it is to study the indication for an operation" (Senn).

By catheterizing the ureters we are able to examine the urine of each side chemically, microscopically, and bacteriologically.

Another very important factor is the condition of the functional action of the kidney, a point which is of the utmost importance in the early diagnosis of kidney disease.

In looking over the literature of death following nephrectomies, we are forced to the conclusion that in many cases sudden death from uræmia shortly after nephrectomies, which were undertaken with all confidence of ultimate success, was due to the failure of determining before the operation the condition of the functional action of the second kidney.

Several years ago a surgeon could be excused in omitting the consideration of this point, as we did not then possess clinical means by which this action could be determined. In the last three or four years a decided progress has been made regarding this point, and as we at first studied the functional action of the heart and stomach, so to-day we are studying the functional action of the kidney, our aim being to determine the insufficiency of the kidney without any other manifestations of disease being present.

It has often been said, and Koenig[8] has lately emphasized it, that there are cases in which it is not possible to diagnosticate with absolute certainty the healthy condition of the kidney. I believe that we can never be *absolutely* certain. Our present methods of diagnosis lead, at most, to the positive recognition of disease of the other kidney.

In cases of negative result we may only go so far as to say that every reason for the assumption of bilateral kidney trouble is wanting. Still the possibility can never be entirely excluded. Notwithstanding the gloomy uncertainty in which we must remain, the case appears entirely different when we are not certain of the condition of the other kidney than when we are certain that both kidneys are diseased.

To discuss in detail how this knowledge is to be obtained would lead too far, exceeding the scope of this paper. Suffice it to say that the cystoscope is a great aid in diagnosis of these cases, and while I fully agree with Henry Morris when he remarks "The cystoscope and the ureteral catheter should be employed with reserve and with great caution in tuberculous disease," I believe that we cannot dispense with this diagnostic means altogether in some of these cases. However, we should always remember that the employment of this method involves a certain danger of infecting a healthy ureter by inserting a catheter into it through an oftentimes infected bladder. On the other hand, the practical experience of Casper (Berlin), Albarran (Paris), Kümmel (Hamburg), and others, who have catheterized ureters hundreds of times, has never shown any permanent untoward results due to ureter-catheterization, provided it was done with proper care and caution.

Pathogenesis and Surgical Treatment of Exophthalmic Goitre.—A. E. Halstead says that, because of the exceedingly good results obtained by the operative treatment of this disease, he holds that it is indicated in all cases where a fair trial of the medical treatment has been made, provided the patient has not become so reduced as to preclude the possibility of withstanding the shock of operation. The operative measures resorted to have been ligation of the thyroid arteries, exothyropexy, enucleation and partial resection. The last is the method to be preferred. The rapidity with which evidence of improvement follows operation varies. There is first an improvement in the general condition, then a change for the better in the nervous phenomena. Tachycardia requires months before actual relief is experienced, and the exophthalmus is frequently last to disappear.—*Medicine.*

IS IT WISE FOR THE REGULAR PRACTISING PHYSICIAN TO SPEND TIME TO INVESTIGATE PSYCHIC THERAPEUTICS?

By R. OSGOOD MASON, M.D.,
NEW YORK.

AUTHOR OF HYPNOTISM AND SUGGESTION IN THERAPEUTICS, EDUCATION AND REFORM.

It is undoubtedly the duty of the physician to be acquainted with all real therapeutic measures. It is admitted that the mind does exercise a decided influence upon the various organs of the body and upon their functions. Certain emotions, for instance, cause the capillaries to dilate, as in blushing; and other emotions, like fear, cause them to contract, and leave the face pallid. Anger may cause the milk of the mother to sicken the nursing child; sudden terror may cause involuntary discharges from bowels or bladder—or it may even cause premature discharge of the fœtus from the pregnant woman. Emotions cause marked physical effects even in animals. The writer recently saw a four-months' colt fœtus, which had been discharged an hour after the pregnant mare had been subject to sudden shock and terror. Such facts, of course, are known to all physicians. The mind undoubtedly does effect physical and physiological changes. What, then, is the limit of its power? Under what circumstances is it effective? Is such power available for therapeutic purposes? Is it worth the time of the scientific physician to investigate these subjects, or must he content himself with his *materia medica?* Undoubtedly physicians now know something of hypnotism, and something of suggestion either with or without hypnotism—but how many really make use of it in any systematic way—or have any decided thought about it or believe in it as a practical therapeutic agent?

It is unnecessary to rehearse the facts regarding hypnotism and suggestion. It took one hundred years—from Mesmer to Charcot—to establish a general belief in the genuineness of the hypnotic phenomena—it may take half a century more to establish its true value as a therapeutic agent; but it will be established. What hypnotism does is to place the patient in a more subjective condition and so make suggestion more effective. It does that in a great majority of cases where it is properly used, and when so used it is helpful to the patient even without suggestion. These are facts which it is not necessary now to spend time in demonstrating; but in using hypnotism for therapeutic purposes unusual phenomena occasionally appear—phenomena which relate to important questions in psychology—such as transferred sensation, from the hypnotizer to the person hypnotized, thought transference and supranormal perception. Is it profitable or wise for the scientific physician to spend time investigating these obscure psychological matters when there is so much still to learn about things that he can cut off and chew and get undoubted effects from? That depends upon the man—some men are so constituted that it is impossible for them to believe anything that contravenes or contradicts things that they have been accustomed to believe or those established by present-day science. There were a great many scientific men in Galileo's time who did not believe that the earth moved—because their science did not so teach. The scientists of London did not believe that Franklin had drawn electricity from a thunder cloud and put it in a bottle—their science had not so taught—and they roared with laughter that such a thing should be seriously broached in meeting; but it is now a part of science—and several other things regarding electricity which were not science then.

The following incident occurred to the writer a few months ago:

A patient in the trance condition while describing scenes which came before her, suddenly stopped and, with evident surprise, said: "I see the body of a young man—he has just died." She looked intently for a moment and then exclaimed, with horror: "Percy X!"—giving the full name—"Percy dead!" Being aroused from her trance, I asked her in a casual way: "Do you know any one by the name of Percy X?" "Yes," said she, "he is my husband's nephew—he is a young physician—I attended his graduation a year ago."

"Have you heard from him of late?" I inquired. "No, not for nine months." "Is his health good?" "Yes—but why do you ask?" "Because you said in your sleep that Percy X was dead." "Percy X dead!" she exclaimed, with an incredulous smile. "If I said that, I must have been making up a story. I am certain that if Percy X were dead I should have known it at once." She went home, told her husband what had occurred, and they agreed that there could be no truth in the statement. But when the husband went to his place of business the following morning he found a letter awaiting him, stating that Percy X died—giving the date—in G— Hospital, and would be buried—giving time and place.

A few days later I wrote to the house physician at G—— Hospital asking for particulars. A courteous reply was received, stating that Dr. X died at the hospital, on the date before mentioned, of tuberculous laryngitis. He had just come from the South and was in the hospital only seven hours before his death.

This patient has given other striking instances of supranormal perception—one no longer ago than May 8 in connection with the eruption at Martinique—no news of which had then reached here. Two other patients have given equally convincing proof of supranormal perception.

These cases have led the writer to believe in the truth of well-authenticated cases that are reported by others—even to telling the time indicated by a hunting-case watch, held in a lady's closed hand—and to conclude that science has not yet got to the bottom of the subject of perception; and it will not get to the bottom of it until it learns how to treat evidence—learns that excessive doubt is just as surely a sign of weakness or ignorance as is excessive credulity, and is really just as great a bar to progress in science. Hypnotism is one of the means through which light has come regarding many subjects of interest in psychology—notably the fact and functions of the sub-conscious mind; and physicians making use of this agent as a legitimate part of their work, as a means of cure, are much more likely to meet with cases of interest in this direction than others who do not use it. There is, therefore, a double motive for using hypnotism as occasion warrants—(1) because it adds a potent agent to the physician's armamentarium, and (2) because in its use he may, at any time, meet with cases of interest bearing upon moot questions in psychology.

At all events, hypnotism and psychic therapeutics have come to stay. Quacks, metaphysical healers, and Christian Scientists make bungling use of the principles involved and yet make cures; not by any means such as they report—a very large proportion must be discounted, but they make cures; and for physicians to stick their heads in the sand and say they don't see them, does not alter the facts. It is for them to open their eyes and see the facts as they are, and show that by these principles, applied with the knowledge and skill which the physician possesses, along with the other means at his command, manifold better results are attained, without the mental stultification which their philosophy entails.

The studies thus brought into the physician's life are full of interest—are refining and elevating—so that it is not only his duty to his patients but a privilege for himself to become intelligent regarding what is being done by the best methods in psychic therapeutics.

CLINICAL STUDY OF A NEW SILVER SALT IN THE TREATMENT OF GONORRHŒA.

By H. M. CHRISTIAN, M.D.,

PROFESSOR OF GENITOURINARY DISEASES, PHILADELPHIA POLYCLINIC; SURGEON IN CHARGE OF THE GENITOURINARY DISPENSARY, UNIVERSITY OF PENNSYLVANIA.

As a result of extensive experience in the treatment of gonorrhœa, genitourinary surgeons have been led to the conclusion that the ideal remedy for local use in this disease should be one whose destructive action upon the gonococcus would not be limited to mucous membrane of the urethra alone, but should possess at the same time penetrating power sufficient to attack the microorganism in the submucous tissue; moreover, these results should be attained without irritating or provoking additional inflammation in the urethra.

Following the discovery of the gonococcus by Neisser, it will be recalled how the profession promptly, turned to bichloride of mercury as offering the most rapid and efficient remedy for the cure of gonorrhœa. The subsequent results following this method of treatment are now a matter of history. Solutions strong enough to kill the microorganism proved highly irritating to the mucous membrane of the urethra, increasing epithelial exfoliation, and thereby favoring still further development of the gonococcus. On the other hand, solutions that were mild and unirritating were found to have little or no effect in destroying gonococci. The same results, but to a much less extent, attend the use of nitrate of silver. To obviate these objectionable features, there has been suggested, in recent years, a large number of nitrate of silver compounds, many of which the writer has certainly found unirritating, but at the same time entirely innocuous, as far as their action in destroying gonococci was concerned.

For the past six months I have been conducting careful clinical investigations regarding the action of a new silver compound in the local treatment of gonorrhœa. This new silver salt is silver vitellin, and was discovered by Dr. A. C. Barnes of Philadelphia, and described by him in the MEDICAL RECORD, May 24, 1902. It is produced from a proteid derived by chemical manipulation of wheat and subsequently combined with silver. The high percentage of silver compound, its extreme solubility, and its intense penetrating action on the tissues constitute its chief scientific points of interest. Silver vitellin contains 30 per cent. of silver, which is more than three times the amount in protargol, the most popular of all the newer silver salts. The solubility of silver vitellin is quite remarkable, one ounce of it being completely soluble in a dessert spoonful of water; consequently, the salt may be employed in solution in any desired strength.

Solutions of silver vitellin do not coagulate albumin or precipitate chlorides; it therefore cannot be chemically changed by contact with mucous membranes or their secretions. My colleague, Dr. Edward Martin, studied the action of silver vitellin solution on catgut, with a view of determining the penetrating power of the compound. It was found that, by immersing a thick strand of catgut in a solution of the salt for a few hours, the gut became impregnated through and through with the silver. This experiment indicates that silver vitellin should exert the effects of silver beneath the urethral mucous membrane where gonococci lodge and are not reached by ordinary agents. It was by reason of its large percentage of silver, and its intense penetrating action, that silver vitellin was expected to prove of great value in the treatment of gonorrhœa.

My clinical investigations as to the value of this compound as a local treatment in acute gonorrhœa, were made in the Genitourinary Dispensary of the University of Pennsylvania, careful records being made in each case with reference to the following points:

(1) Effect of the remedy upon the discharge from the urethra.

(2) Time at which the gonococci disappeared after treatment was first employed.

3. Whether the injection caused any pain in the urethra, or gave rise to any signs of urethral irritation.

4. Number of cases presenting any complications.

5. Length of time required to cure.

In conducting these investigations no other drug but silver vitellin was employed; it was prescribed in the following manner: During the first week, injections of a 2 per cent. solution, with the ordinary two-drachm hand syringe, were used four times daily, the solution being held in the urethra for five minutes. In the second and third week 5 per cent. solutions were used in the same manner; in the fourth, fifth and sixth weeks as high as 10 per cent. solutions were used without causing any pain or irritation. When the urethritis became total, the hand injections were temporarily discontinued, and daily total irrigations with the salt were employed, beginning with 1 to 2,000, increasing in many cases to 1 to 500 solution. Deep instillations of 1, 2, and 5 per cent. solutions were made in quite a number of cases without causing any inflammatory reaction. The remedy was employed in 100 cases, in fifty of which the records in the dispensary case book are incomplete, owing to the failure of the patients to return at regular intervals and report as to their condition. This is a well-known difficulty attending all dispensary practice; at the same time it is fair to presume that a large majority of these cases failing to return must have been distinctly benefited, if not entirely cured, by the prescribed treatment.

We have, up to the present time (July), a complete record of the action of the silver salt in forty-eight cases. The clinical investigations in these cases were conducted in a most rigid manner, the patients reporting to the dispensary every other day, when careful notes were made as to the amount of discharge and the condition of the urine; at the same time a microscopical examination of the discharge was made. Of these forty-eight cases, there were cured forty-five; unimproved three. The direct effect upon the amount of discharge was as follows: Prompt cessation in thirty-one cases; more gradual reduction in fourteen cases, and very little effect in three cases.

Gonococci disappeared in two days in four cases; in four days in eight cases; in six days in eight cases; in eight days in five cases; in ten days in ten cases; in fourteen days in eight cases; persisted over three weeks in five cases.

In this connection it is well to note that in four cases, where there occurred a recurrence of discharge due to indulgence in alcohol, microscopical examination failed to show any gonococci. This seems to be a most interesting point and one worthy of further investigation; it goes a great way toward demonstrating the penetrating power of the drug and its action in destroying gonococci in the submucous tissue.

Complications occurred in five cases, namely, acute prostatitis in one (1) and epididymitis in four. It is only fair to state that two of the cases affected with epididymitis presented signs of an old chronic seminal vesiculitis, resulting from previous attacks of gonorrhoea.

Concerning the duration of the disease, it was found that in nine cases there was an apparent cure in two weeks. Of the remaining, seventeen cases were cured in three weeks; twelve cases were cured in four weeks; seven cases were cured in six weeks; three cases were cured in eight weeks.

The results obtained in our cases at the University Hospital have convinced me that we have in silver vitellin the best silver compound ever offered to the profession for the treatment of gonorrhoea, for the following reasons:

1 That it is absolutely free from any irritating properties, solutions as high as 5 per cent. causing no discomfort.

2. That the gonococci on and beneath the urethral mucous membrane are rapidly destroyed.

3. The amount of urethral discharge is in a majority of cases at once lessened in a marked degree.

4 The actual duration of the disease is shorter than is obtained by the use of any other silver salt. In our cases thirty-eight were cured in from two to four weeks.

My thanks are due to my assistant, Dr. Otto H. Foerster, for his careful and accurate work with the microscope done in connection with this clinical investigation.

1344 Spruce Street.

PULSE AND RESPIRATION AT AN ELEVATION OF 10,200 FEET, AS ASCERTAINED BY THE EXAMINATION OF ONE HUNDRED SUBJECTS.*

By MAURICE KAHN, M.D
LEADVILLE, COLO.

In submitting the following tables for your consideration, I confess frankly that the slight acceleration of the pulse is less than I expected. Notwithstanding that the increased frequency of the pulse and respiration is inconsiderable, the tables are not less interesting nor less valuable.

I am keenly cognizant of the fact that the number of subjects examined is insufficient to permit of the deduction that the results obtained are the norm for an altitude of 10,200 feet, yet I think they should not be treated indifferently, for they are not unimportant or worthless if interpreted correctly. And they do indicate one thing, at least, viz., that the almost universal fear of heart failure at high altitudes must be groundless. I refer, of course, to normal hearts.

For illustration we often hear of the dangers of high altitudes in cases wherein the system has some unusual strain placed upon it. The more frequent examples being pulmonary tuberculosis, pneumonia, and all major surgical operations. I think this opinion prevails not only in the minds of laymen but also in the minds of many of the profession.

How often do we hear it said that it is unsafe or hazardous to perform cœliotomy at so high an altitude (partly by reason of the resulting shock to the system and partly on account of the depression of the heart consequent upon the administration of the anæsthetic)? And how often do we hear it said that a crippled lung will not withstand the increased labor that such a high altitude *per se* imposes?

In a former article† I had occasion to make a plea for the trial of very high altitudes in incipient phthisis. Further experience with these cases has convinced me that I am now justified in advocating the practice which three years ago I suggested as a tentative procedure.

The purpose of this paper, however, is not to promulgate the merits of high altitudes, but merely to call your attention to the results of the examination of the pulse and respiration of one hundred normal persons (determined normal by strict physical examination and scrupulous questioning) at 10,200 feet.

A careful perusal of the accompanying tables will show that the rates vary but slightly from the norm at altitudes much lower—even two miles lower—than the one at which these records were taken. In every instance the record was taken in the sitting position, at least two hours after the ingestion of any food or stimulant, and the subject was in as near perfect mental rest as could be obtained—fear, apprehension, and mental excitement having been eliminated.

Furthermore, the subject had been resting, physically, for some minutes, so that no effect from running or walking could be operative.

One hundred cases examined—eighty-three men; seventeen women.

Average age for the one hundred, 31.82 years.

Average pulse for the one hundred, 76.50 a minute.

Average respiration for the one hundred, 20.48 a minute.

Average age for eighty-three men, 32.97 years.

Average pulse for eighty-three men, 76.36 a minute.

Average respiration for eighty-three men, 20.28 a minute.

Average age for seventeen women, 26.29 years.

Average pulse for seventeen women, 77.17 a minute.

Average respiration for seventeen women, 21.41 a minute.

The youngest woman was eighteen years of age.

The eldest woman was forty-five years of age.

The youngest man was nineteen years of age.

The eldest man was sixty-four years of age.

The lowest pulse was 60, in a man twenty-nine years of age.

The lowest respiration was 15, in a man twenty-five years of age.

The highest pulse was 92, in a man twenty-one years and in a man forty-five years of age.

The highest respiration was 26, in a man sixty-four years of age.

The lowest combination, proportionately, of pulse and respiration was 72 - 15, in a man twenty-five years of age.

The highest combination, proportionately, of pulse and respiration was 92 - 23, in a man twenty-one years of age.

THE PATHOLOGY AND THE CURABILITY OF PULMONARY PHTHISIS.

So commonly is destructive disease of the lungs of tuberculous origin that the terms phthisis, consumption, and tuberculosis have, in the minds of not a few, become synonymous, and are not rarely used interchangeably. It is, however, important from both the prognostic and the therapeutic standpoint to recognize the distinction. Lung-destruction may result from a variety of causes, of which tuberculosis constitutes but one, albeit the preponderating one. Other less common causes are suppuration, syphilis, actinomycosis, and bronchiectasis. The outcome and treatment must necessarily vary in accordance with the etiological factors in the individual case.

An interesting presentation of this subject has recently been made by Prof. D. von Hansemann (*Berliner klinische Wochenschrift*, August 11, 1902), who points out that, although the curability of pulmonary consumption has long been maintained, there have at all times not been wanting voices in contradiction. Recent anatomical investigation, however, has demonstrated such curability beyond peradventure of doubt. At the present time there is a wide diversity of opinion as to the proportion of cases in which cure takes place, as the results of post-mortem examination will vary in accordance with the source of the material that comes under observation. Thus, if the patients have been largely old people, the proportion of cures will obviously be the greater.

That pulmonary phthisis is by no means always tuberculous is pretty generally recognized. Destruction of lung tissue may be due, for instance, to bronchiectasis resulting from congenital weakness of the walls of the bronchial tubes. At the same time the pulmonary structure itself may be imperfectly developed. The bronchial tubes undergo dilatation, and the lung tissue disappears. The weakness of the bronchial tubes may also develop later in life, in consequence of chronic bronchitis, or the dilatation may be due to retraction secondary to inflammation of the pulmonary structure.

So-called fibroid phthisis may be of varied origin, but it is principally a result of processes attended with chronic lymphangitis. It includes pneumonoconiosis, carnification of the lung after imperfectly-resolved pneumonia, fibrous lymphangitis associated with chronic bronchial catarrh, and idiopathic reticular and trabecular lymphangitis. Ulcerative phthisis may be independent of tuberculous processes, although it may be secondary to fibrinous pneumonia, dissecting pneumonia, and influenzal pneumonia. Syphilitic phthisis, as well as actinomycotic phthisis, should always be taken into consideration.

Tuberculous phthisis is characterized not so much by the presence of tubercles as by the presence and activity of tubercle bacilli. These may give rise, further, to hyperplasia and inflammatory infiltration, with cicatrization and ulcerative destruction, and be complicated by mixed infection. They may find lodgment in the bronchial tubes, in the alveoli, in the neighborhood of vessels, or in the lymphatic apparatus of the lungs. Accordingly, various morbid processes will result, differing in clinical manifestations, in course, in prognosis, and in the anatomical findings, and also requiring different treatment. In the opinion of Hansemann, true tuberculosis of the lungs begins almost invariably at the apices. When this is not the case, the explanation will be found to reside in some special condition, such as secondary infection of a primary bronchiectasis, pneumonoconiosis, fibrous lymphangitis, gummatous foci, etc. The phthisis complicating diabetes also is frequently not localized at the apex, as well as that following influenza, fibrinous pneumonia, and traumatism.

The phthisical process may begin on the mucous membrane of a bronchial tube, and it may throughout give rise especially to caseous, bronchitic, or peribronchitic foci. It may be acute, occupying weeks or months—the lung on section presenting an appearance of miliary or somewhat larger nodules, the largest being situated at the apices and in the upper lobes, and which in reality are divided bronchial tubes inflamed and filled with cheesy matter. The larger are surrounded by tubercles with giant cells. The intervening lung tissue may be free from inflammatory changes. Signs of cicatrization are not found, and cure does not take place. When, however, the process pursues a chronic course, slate-colored cicatrices form. The apparent nodules are not so widely disseminated, but are collected in groups about a central nodule, in which cicatrization takes place. In this way cure may result.

Cheesy hepatization may be lobular or lobar. It may result from antecedent pneumonia and may increase by extension of the pneumonic process. The cellular contents of the alveoli undergo caseous degeneration and the walls of the alveoli become necrotic. Small foci may become surrounded and penetrated by cicatricial tissue, while large foci must become encapsulated by connective tissue, in order that cure may be brought about.

The development of a cavity is not due to any single process. It may result from the disintegration of a focus of cheesy hepatization, or from tuberculous ulceration of a large bronchial tube. Frequently mixed infection exists, causing rapid disintegration, and resulting in florid phthisis, without any tendency to cure. Cavities may, however, be obliterated by contraction of the cicatricial tissue by which they are surrounded, or by conversion into a fibrous structure of the granulation tissue by which they are lined and extension of epithelium from a communicating bronchial tube.

Miliary tuberculosis should be separated from pulmonary phthisis. It may develop from a circumscribed phthisical process in the lung, but it never gives rise to such a process. It is part of a generalized tuberculosis, and cure is out of the question.

It will thus be seen that some tuberculous processes may undergo cure through the formation of cicatricial tissue, and this occurs in three forms: (1) cicatrices presenting no trace of the tuberculous process; (2) dense, slate-colored cicatrices containing calcareous cheesy foci; (3) cicatrices containing cavities the size of a pea and larger. The first represent a definite cure, but it has long been known that active and virulent tubercle bacilli may persist for an almost indefinite time in encapsulated calcareous and caseous foci. Even under the latter condition, however, it is scarcely possible for infection to take place. The same statement is applicable to cavities surrounded by dense fibrous tissue

The differentiation of syphilitic cicatrices in the lungs from the cicatrices due to tuberculosis is based upon the situation of the former elsewhere than at the apices and upon their radiate arrangement from various centers, whence they extend to the pleura, causing lobulation of the lung through retraction. Gummata undergo absorption and never leave permanent caseous or calcareous foci. Syphilis of the lung sometimes transforms the entire organ into dense slate-colored cicatricial tissue, radiating from a central focus at the hilus of the lung to the periphery. The presence of syphilitic cicatrices in other organs constitutes valuable collateral evidence. Pneumonia does not, as a rule, leave cicatrices in the lung, but if frequently repeated there may form ill-defined irregular reticulated lines and processes of connective tissue surrounding lung tissue containing air or atelectatic parenchyma. They may be black or unpigmented, and they are rarely situated at the apices. Under all circumstances importance must be attached to the previous history when this can be obtained.

THE LATENCY OF ABSCESS OF THE BRAIN.

The symptoms of abscess of the brain are essentially those of a neoplasm, or a foreign body, associated at times with those of suppuration. Often, also, a source of infection can be readily discovered, but this is not always so; and at times the phenomena peculiar to abscesses in general are wanting. The recognition, and especially the localization, of a brain tumor may be exceedingly difficult, and if a primary focus of suppuration be not evident, a diagnosis of cerebral abscess may be impossible. Just such a contingency occasionally arises in consequence of the latency that sometimes characterizes the symptoms of this latter condition. Cases are on record in which an abscess of the brain has been present and has remained unrecognized for many years.

A case belonging in this category, and which besides aroused suspicion of atropine intoxication has recently been related by Dr. E. Aufrecht (*Deutsches Archiv fur klinische Medicin*, Vol. 72, Nos. 5 and 6). A man forty-nine years old was rendered unconscious by having a number of sacks of sugar fall on him. He subsequently complained of severe pain in the right side of the chest and had transitory hemoptysis. When examined four and again five months later no physical abnormality was discovered, although the pain persisted. The latter was still present after the lapse of five years, and with it had become associated frequently-recurring attacks of oppression of the chest, a sense of constriction and shortness of breath. As there was no objective evidence of disease, 1-60 grain of atropine at night was prescribed. On the following day the patient began to feel badly, and on the next succeeding day he was unable to sit up. He complained of headache and confusion, and was scarcely able to speak. Slight twitching was, from time to time, noticeable in the right arm, and the pupils were dilated. As the new symptoms had appeared after ingestion of the first dose of atropine, and there was some doubt as to the amount of the drug the patient had taken, atropine intoxication was for the moment suspected, but this suspicion was soon dispelled by the further development of the case. A day later the patient complained of headache for the first time, and also of vertigo, with difficulty in finding words for speech. The pupils were no longer dilated, and they reacted well. On the next day the patient was seized with violent convulsions, involving the left side of the face and the left arm, without loss of consciousness. There was some difficulty in swallowing liquids, but no vomiting. The pulse-frequency was neither increased nor diminished, and the temperature was not elevated. Vision was unimpaired. Speech became gradually more difficult, but the patient indicated by gesture that he was left-handed. He became restless and threw himself about in bed. He complained of oppression of the chest, great difficulty in breathing and pain, followed later by numbness and weakness in the left arm. Pain appeared also at the left shoulder and the knees. The left arm eventually became paralyzed and the left leg paretic. Finally the right side of the face was the seat of spasm for an hour. The paralysis of the left side of the body became complete. Gradually consciousness was lost. The motility of the body became progressively less, and ingestion of food grew increasingly difficult until death took place on the twenty-fourth day of the disease.

On post-mortem examination the left lung and the upper lobe of the right lung were found to be adherent to the chest-wall, and the lungs themselves were œdematous. The convolutions of the right cerebral hemisphere were flattened, and exhibited a rectangular bluish-black area three-fourths by one-half inch in size, occupying the breadth of the anterior central convolution at the highest point of its convexity. This corresponded to an almost globular abscess about two inches in diameter, extending to the right lateral ventricle, and whose walls, one-third inch thick, were lined with false membrane well provided with newly-formed blood vessels. The lateral and the third ventricles contained greenish-yellow pus, and their ependyma was turbid. It is believed from the density and the vascularity of the false membrane in the present case that the inception of the abscess dated back to the traumatism five years previously, and that the onset of the symptoms, coincidently with the administration of the first dose of atropine, was merely accidental.

SUICIDE IN THE UNITED STATES DURING 1901.

THE *Spectator* of August 14 has a paper contributed by Mr. Frederick L. Hoffman on the suicide record of 1901. Statistics clearly show that there is a gradually increasing tendency to self-destruction in the cities of the United States. The rate per 100,000 of population has changed from 15.8 in 1900 to 16.6 during 1901. The annual compilation of statistics of 135 cities with more than 30,000 inhabitants by the United States Commissioner of Labor gives a suicide rate of 16.3 per 100,000 for the year 1900. while for the country at large a somewhat lower rate prevailed. Mr. Hoffman gives a table in which the returns for fifty cities have been brought together, the table showing, first, the average actual and relative mortality from suicide in each of the cities during the decade 1891—1900; and second, the actual and relative mortality from suicide during 1901.

This table points out that the average mortality from suicide during 1891—1900 was equivalent to a rate of 15.7 per 100,000 of population. During the year 1901 the rate was 16.6, an increase of 0.9 per 100,000 of population. The city in which suicide has been of most frequent occurrence during the ten-year period is St. Louis, Mo., while the rate was lowest in Fall River, Mass. In the former city the rate was 25.7 per 100,000, against only 2.9 in the latter. During the year 1901 the suicidal frequency was not exactly the same as established by the ten-year average, but, generally speaking, the cities subject to an excessive mortality from suicide maintained their respective ratios during successive years. Of the fifty cities thirty-one show an increase in the rate, while nineteen show a decrease, when the year 1901 is compared with the average for the preceding decade. The city having the highest ratio during 1901 was Hoboken, N. J., while the city having the lowest ratio was Fall River, Mass. The ten cities with the largest suicidal frequency are St. Louis, Mo.; Chicago, Ill.; Hoboken, N. J.; Oakland, Cal.; New York City—Manhattan and the Bronx; Milwaukee, Wis.; Cincinnati, O.; Newark, N. J.; New Orleans, La., and Brooklyn, N. Y. The aggregate returns of the fifty cities compared to individual years since 1890 show that the increase in the suicide rate has been gradual and persistent. The rate for 1890 was 12.0 per 100,000 of population, increasing to 16.6 by 1901. The rates, however, were highest during the two years 1897-8. If the rate prevailing during the first six years be compared with the last, it is seen that the average mortality from suicide was 14.4 per 100,000 during 1890—95, against 16.5 during 1896—1901.

Mr. Hoffman is particularly interested in the suicide question as it relates to the insurance companies, and gives the mortality from suicide experienced by the New York Mutual Life from 1843—1885 and from 1886—1898.

During the first period, ending with 1885, of the deaths from all causes suicides formed 1.9 per cent., the percentage having increased during the second period to 2.4 per cent. In the aggregate there have been 991 suicides among males during the period under observation, and the relative increase in the proportionate mortality has been 26 per cent. If separate age groups be considered, it appears that at ages under forty-five the proportion of suicides to the total mortality increased from 2.1 per cent. to 3.9 per cent. At ages forty-five to sixty the increase was from 2.4 per cent. to 3.2 per cent, while at sixty and over there was a decrease in the proportionate mortality from 1.0 per cent. to 0.7 per cent. Among females the proportion of suicides was 0.2 per cent. of the deaths at all ages during the first period under observation. The proportionate mortality from this cause increased to 0.9 per cent during the period ending with 1898.

The subject of suicide, viewed from various standpoints, has been fully discussed, at different times, in the MEDICAL RECORD. The figures provided by Mr. Hoffman are of the greatest interest and importance, and plainly demonstrate the unpalatable fact that the suicidal tendency is surely on the increase in the United States. A comparative table of suicide statistics of Europe and America would be of much value.

Undoubtedly the wear and tear of modern life has much to do with the increase of suicide. This is clearly brought out by the fact that suicides are far more frequent in cities than in the country. Again, it cannot be doubted that alcohol plays a conspicuous part in the impulse toward suicide, while at the same time there is among certain races an undeniable and peculiar suicidal idiosyncrasy. Upon the whole, however, it may be confidently asserted that modern civilization, with its nerve-racking stress and strain, is chiefly responsible for the increase in the tendency to self-destruction.

HETEROGENESIS.

In these days of wonderful and revolutionizing theories, as regards the doctrines of evolution, Dr. Charlton Bastian has recently advanced one more remarkable than any yet brought forward.

Dr. Bastian, who will perhaps be remembered as a man who declared that he had discovered spontaneous generation to be no myth but a sober fact—a statement shown to be false by Professor Tyndall—now comes forward with the assertion that one species can be suddenly transformed into another; that the eggs laid by one creature may bring forth the young of another.

The Royal Society of Great Britain is so sceptical of Dr. Bastian's claims that it has refused him a hearing, an attitude somewhat adversely criticized by the London *Hospital*, which holds that the recent publication of Dr. Bastian's views and the refusal of the Royal Society to give them a hearing may serve to raise very interesting and important questions concerning the extent to which it may be incumbent upon philosophers to take note of opinions or assertions, in relation to the subject matters of their studies, which appear to be subversive of doctrines almost universely held to be true.

Dr. Bastian, in illustration, of heterogenesis, declared that he had witnessed the transformation in the course of three or four days of the entire contents of the egg of hydatina serita into a large ciliated infusorium belonging to the genus otostoma. To admit the possibility of such a happening would be to shatter the framework of modern biology, but the *Hospital* is of the opinion that the wiser policy on the part of the Royal Society would have been to discuss the question, and point out the sources of error by which, in their judgment, the recorded experiments must have been invalidated, rather than to treat the matter with contemptuous incredulity.

It should be borne in mind that almost all epoch-making discoveries have been at first pooh-poohed, and that the men who have advanced new and startling theories—many of which afterward were shown to be true—have been laughed at for their pains. At any rate, a discussion of Dr. Bastian's theories by the leading scientists of Great Britain—even if it had proved his conclusions fallacious—might have been the means of bringing out new facts, and of throwing more light upon the problem of the production of life.

Marriage Among Eminent Men.

Professor Edward L. Thorndike, in the *Popular Science Monthly* for August has a well-considered study of this matter. Says the Professor:

"The failure of the human race to reproduce at the top has been the cause of frequent complaints by students of society. The necessity of improving the human species by perpetuating desirable strains and restricting the increase of defectives, delinquents and dependents has impressed every thoughtful observer of human affairs and led him to wonder to what extent various classes of men share in producing the next generation. The reply has commonly been the cheerless dogma that the top strata of society are constantly dying out, that gifted men and women marry much less and later and have fewer children than the thoughtless multitude.

"I have tested two of these claims in the case of eminent men of our own country. The results have more than a curious interest. The well-known 'Who's who in America' contains the names of about ten thousand men. Some of these are grotesquely out of place, and many eminent men are missing from the list. But if we select one thousand or more, we have a body of men surely of the top hundredth if not of the top five hundredth of men of their age. Their attitude toward marriage will give an idea of the attitude of men who have shown superiority over at least 99 per cent. of their fellow men. The facts cannot be stated with absolute precision, since a large percentage of them do not make any report at all concerning their conjugal condition. In an investigation of a number of these cases it was found that three-fourths were married. . . . " "There is thus little or no avoidance of marriage peculiar to gifted men. The contrary belief seems one of the numerous scientific superstitions. If we examine age at marriage, we may justify the claim that gifted men marry not only almost as commonly, but also as early as the rank and file of those who have reached the age of forty-four and married before forty-five, 22.2 per cent. married before the age of twenty-five, 43.3 per cent. between twenty-five and thirty, 18.7 per cent. between thirty and thirty-five, and 15.8 per cent. between thirty-five and forty-five. The corresponding figures for the general male population of the United States are 22.7, 41.0, 23.1 and 13.1." Obviously, therefore, the gifted men marry at almost the same ages as the multitude.

The Charity Organization Society and Consumption.

The Charity Organization Society, which of late years has done much for the amelioration of the poorer classes and attained conspicuous success by means of its Tenement House Committee, has now taken up the tuberculosis question, and has appointed a committee on the prevention of tuberculosis consisting of twelve representative physicians and fifteen others who are concerned with the disease, viewed from a social standpoint.

The committee intend to first make a thorough investigation of some of the social aspects of tuberculosis. Tuberculosis for long has been closely studied, bacteriologically and clinically, and much has been learned of the physical aspects of the disease. But the social aspects of the malady have been comparatively neglected—for instance, the subject of environment, or the relation between living apartments and the victims of the disease, has been by no means exhaustively investigated.

A systematic effort will also be made to ascertain how far infection can be prevented by instruction in the nature of the disease and in the character of the precautions which should be taken to prevent its spread.

In addition to a study of the social aspects of tuberculosis, the committee has stated that its objects are as follows: 1. The promulgation of the doctrine that tuberculosis is a communicable, preventable and curable disease. 2. The dissemination of knowledge concerning the means and methods to be adopted for the prevention of tuberculosis. 3. The advancement of movements to provide special hospital, sanatorium, and dispensary facilities for consumptive adults and scrofulous and tuberculous children among the poor. 4. The initiation and encouragement of measures which tend to prevent the development of scrofulous and other forms of tuberculous diseases.

The Presenility of Americans.

Dr. A. McLane Hamilton published, a short time ago, an essay entitled "The Neurotic Indications of Presenility," which the *British Medical Journal* of August 6 makes the text for a leading article. The editorial in question commences by saying that a large proportion of the able-bodied citizens of the United States, if we may judge from the amount and variety of tonics and restoratives which seem to find a ready market among them, are "born tired."

Dr. Hamilton asserts that Americans of the present day exhibit a decided tendency to grow old before their time, a fact which he attributes to their "over-use of the nervous system." Further than this, Dr. Hamilton declares that Americans do not last so long as Europeans, and that this premature decay is largely due to the struggle for the rapid accumulation of wealth or for the gratification of ambition, for both of which cravings the New York alienist opines that the over-stimulating quality of the American newspaper is chiefly responsible. It is undoubtedly true that the storm and stress of life beats more strongly in cities of this continent than in Europe, but that the American generally becomes worn out sooner than the inhabitants of the other side—although often asserted—has never been satisfactorily proved.

It should be remembered that a larger proportion of Americans live in the country and in small towns than do the English, and this should equalize the conditions of life in these countries. For although the life in the cities of the United States may be more strenuous and nerve-wearing than in those of Great Britain, yet, on the other hand, a much larger proportion of the British people are inhabitants of cities. The general health of the American people is, probably, as good, if not better, than that of Europeans. It cannot, however, be denied that all the nations in the van of civilizations are becoming more and more neurotic, and that the trend of modern methods of business and pleasure is to augment these evils.

The writer in the *British Medical Journal* admits and deplores the fact that John Bull is also becoming neurotic, and advises the Britishers to take to heart and to benefit by Dr. Hamilton's remarks anent his own countrymen.

THE EVOLUTION OF A MEDICAL PUBLISHING HOUSE.

A notable example of the continuance of an important establishment through several generations is afforded in a sketch of the foundation and growth of the publishing house of Wm. Wood & Company, which we find in *The Publishers' Weekly* of August 30, 1902. This house, which is there said to be the oldest publishing house in New York, with the single exception of the Methodist Book Concern, had, like most other things of substantial worth, a very modest beginning.

In 1804 Samuel Wood, born in Oyster Bay, L. I., in 1760, who had been a school teacher in Long Island, opened a bookstore in Pearl street in this city. Two years later, in 1806, he published his first book, "The Young Child's A B C," a little affair of sixteen pages, about three inches square. In 1815 Samuel Wood took into partnership two of his sons, Samuel S. and John, and soon began the publication of a periodical called *The Friend of Peace*. In 1817 another son, William Wood, was taken into the firm, John Wood retiring. About this time the first medical books were published by the house, the junior partner being especially interested in this department. The founder of the house died in 1844, and his son, Samuel S. Wood, died in 1861. The other son, William, continued the business alone for two years, and then associated with himself his son, William H. S. Wood, the senior member of the present firm, the name, Wm. Wood & Company, dating from this year.

From about 1861 the publication of general books began to be discontinued, and, with few exceptions, none but medical books have been published by the house for a quarter of a century. In 1866 the publication of the MEDICAL RECORD was begun, and this was followed by the *American Journal of Obstetrics and Diseases of Women and Children* in 1868. The history of the house since this date has been one of quiet but steady progress. It is of interest to note, however, that the first medical book to be sold by subscription was the American edition of Ziemssen's "Cyclopædia of the Practice of Medicine," the publication of which was begun by this firm in 1874.

INCREASE OF JEWS IN NEW YORK CITY.

The Jews are a race that increase and multiply. They are both prolific and tenacious of life, the latter being greatly due to their temperate habits, and to their observance of the sanitary ordinances of their religion. The Jews in the United States have increased in number from 130,000 in 1891 to 1,058,000 in 1901—a truly remarkable showing. Of course the immigration of Jews of late years has been very heavy, especially from Austrian and Russian Poland. In fact, something like seven times as many Jews entered this country during the past ten years as during all previous years, and at the present time America contains twice as many Jews as does Germany.

The majority of these immigrant Jews have gone no farther than New York City, the consequence being that the Jewish population of the metropolis is greater than that of any city in the world. An article in a recent issue of the *Jewish World* places the number of Jews in New York at 600,000, and although these figures are probably exaggerated, still there are in the neighborhood of 500,000 members of the Hebrew race in Greater New York; and as all but a relatively few are in the Borough of Manhattan, that portion of the city has one person in nearly every four a Jew.

News of the Week.

Typhoid Fever is still prevalent in Philadelphia, 120 cases having been reported for the week ending September 13, the same number as that of the previous week. In Chicago there are signs that the disease may be declining. During the week ending September 13 there were forty-three deaths, twelve less than during the previous week, and in the Cook County Hospital there were only 240 cases under treatment at the close of the week, as compared with 373 three weeks previously. Another fact that is construed by the Board of Health as an indication that the height of the epidemic has been reached is the increasing duration of the disease in the fatal cases. The average duration of the sickness in the fatal cases in August was seventeen days. During the first thirteen days of September it was twenty-two days, and during the last week it was more than twenty-seven days. As the average period of the incubation of the disease after infection with the poison is two weeks, these latter figures show that the infection occurred at least forty-one days previous, or in the latter part of July, when the water supply was badly polluted. Unless the water supply should again become seriously polluted, there is reason to believe that the backbone of the typhoid epidemic is broken. It is reported that typhoid fever prevails in the garrison on Fisher's Island, off New London, dating from the time of reinforcement of the garrison for the war manœuvres. It is officially reported that there have been sixty-eight cases among the soldiers on Fisher's Island, twenty-five of them in one company. It is also said that there were thirty typhoid cases in the post hospital on September 19. Only one death had occurred to that date, the attacks being unusually light. In New York City there is the usual autumn prevalence of the disease, the total number of cases reported up to September 6 being 1,737, 407 more than at the corresponding date last year, but the mortality has been less—393 deaths, as compared with 401 in 1901. Since September 6 there has been a decrease in the number of cases reported.

Coney Island Hospital Closed.—The Reception Hospital at Coney Island, which was open in the summer, has been closed, and will not reopen until May. Hereafter all accident cases at the island will be looked after at the Kings County Hospital in Flatbush.

The St. Louis Antitoxin-Tetanus Epidemic Recalled.—A woman in St. Louis has brought suit in the Circuit Court against the city and the Board of Health for $16,000 damages. She alleges that two of her children died last October of tetanus, resulting from the use of impure antitoxin furnished by the city.

Gift to a Philadelphia Hospital.—It is announced that Mr. Meyer Guggenheim of New York has added $20,000 to his gift of $60,000 for the erection of a hospital for private patients on the grounds of the Jewish Hospital at Logan, a suburb of this city. The structure will have four stories.

Quarantine Against Cleveland.—The Board of Health of Sharon, Pa., has declared a quarantine against Cleveland, Ohio, on account of the prevalence of smallpox in the latter place. Cleveland rejoices in the possession of a health commissioner who does not approve of vaccination as a preventive of smallpox. He has recently issued an order that in all families where smallpox is discovered and where there is a dog or a cat the animal must be killed. He contends that cats and dogs are the worst distributers of the smallpox germs that can be found. The hair of either animal may be filled with the germs, he says, and then a child may play with the pet. The result is another new case of smallpox. If the dog is permitted to run at large, the danger is more than doubled. The health officer's attitude toward vaccination had endeared him to all the antis, and he was hailed by them as the one just man in the wicked assembly of doctors, but this new move will destroy his popularity with them. If forced to choose between two evils, the anti would always rather have a child inoculated with the loathsome vaccine disease than have a dog or a cat hurt.

International Conference on the Prevention of Tuberculosis.—This conference will be held in Berlin October 22-26, 1902, and Dr. Freudenthal writes that a cordial invitation to attend the meetings is extended to all Americans interested in the subject.

French Urological Congress.—The French Urological Association will hold its sixth annual meeting in Paris on October 23, 24 and 25, under the presidency of Professor Guyon. The chief question proposed for discussion is the Indications and Results of Nephrectomy. The discussion will be opened by two papers read by MM. Forgue and Michon. The secretary of the Congress is Dr. E. Desnos, 21 Rue de Rome, Paris.

Cholera is still prevailing to an alarming extent in Egypt. On September 18 there were 858 new cases of the disease reported and 784 deaths. Fifteen of these deaths occured in Cairo and 24 in Alexandria. The total number of cases reported throughout Egypt from the beginning of the epidemic to September 21 was 31,765, and of deaths, 26,554.

Dr. William H. Bates, an ophthalmologist of this city disappeared from his home about two weeks ago, and no trace of him has since been discovered.

Garnault's Skin Lesion Tuberculous.—Dr. Barai of the Pasteur Institute has recently reported that guinea pigs inoculated with skin from the arm of Dr. Garnault, who inoculated himself with bacilli from a consumptive cow, have developed tuberculosis.

Site for the New Jersey Tuberculosis Hospital.—Five hundred acres of land have been purchased at Glen Gardner, in Hunterdon County, for a site for the proposed New Jersey State Hospital for Consumptives. The ground is about half a mile from the New Jersey Central Railroad station at Glen Gardner, and is easily accessible from all parts of the State. The commission charged with the selection of a site and erection of the hospital is composed of Dr. Charles J. Kipp of Newark, Dr. Austin J. Scott, President of Rutgers College, New Brunswick; Col. E. A. Stevens of Hoboken, Dr. O. O. H. Sproul of Flemington, Dr. Elmer Barwis of Trenton, Dr. James S. Green of Elizabeth, Frank L. Shepard, Superintendent of the Pennsylvania Railroad, and Dr. Walter Jones of Camden. The work of the commission must be approved by Governor Murphy before work on the building can be begun.

An Operation Begun in One Hospital and Ended in Another.—The papers report the case of a man who was taken to the Polyclinic Hospital suffering from intestinal obstruction, for which an operation became necessary. This was begun at one o'clock in the morning, and after the abdomen had been opened an accident happened to the sterilizer, rendering it impossible to continue. The abdomen was therefore closed temporarily, and the patient was transferred to Bellevue Hospital, where the operation was completed. The man did well at first, but sank suddenly and died a few hours later.

University of Pennsylvania.—Dr. John Marshall, professor of chemistry and toxicology and dean of the Medical Department, will decline re-election to the office of dean, a position he has held for eight years, in order to devote himself more closely to his teaching work.

Philadelphia County Medical Society.—At a stated meeting held September 10, Dr. M. H. Fussell read a paper entitled "The Value of Diphtheria Antitoxin," and Dr. L. Napoleon Boston a communication entitled "Leucocytosis in Lead Workers."

Tri-Medical Society of Alabama, Georgia, and Tennessee.—The fourteenth annual meeting of this society will be held, as previously announced, in Birmingham, Ala., on Tuesday, Wednesday, and Thursday, October 7, 8, and 9, 1902, under the presidency of Dr. J. C. Le Grand of Birmingham. An attempt has been made to have the discussion of sociological questions an important feature of this meeting, and with this in view the members have been urged to present papers on these subjects, especially on the public relation of tuberculosis, its prevention, and its cure, the physical and mental development of boys and girls, evils of our methods of education, and its effects on physical and mental development, the feeble-minded and care of same, crime and its causes, the criminal and his development, the negro and his various relations to the white race—physically, morally, and intellectually, etc.

Official Journals of State Societies.—A noticeable tendency in medical journalism at the present day is that toward the establishment of official organs of the various State societies. Several of the larger States already have such periodicals, the latest being the *Journal of the Michigan State Medical Society*, the first number of which is dated September, 1902. Articles published in a monthly journal are certainly more apt to be read than those appearing in a bound volume of transactions, but unless the journal can secure a wider circulation outside of the society's own members, this advantage will be more apparent than real.

The San Francisco Board of Health.—A breezy report, and one outside of the usual order, is that of the Board of Health to the Mayor of San Francisco. It will be remembered that this mayor, whose name is Schmitz, summarily discharged the Health Board last March, the reason being that that body had had the courage to tell the truth regarding the existence of plague in the city. Fortunately, the courts intervened and checked Mr. Schmitz, the old Board was continued, and this report is devoted in great part to its review of the Mayor's conduct. At the time this report was made there had been fifty-seven cases of undoubted plague in San Francisco; from that date, June 30, to August 23, there were eleven additional cases, making the total sixty-eight.

The President of Cuba Thanks Major Gorgas.—On Saturday last Major Gorgas, chief of the Sanitary Department in Havana during the American occupation, who sails to-day for New York, was entertained at a farewell dinner by President Palma. The President took the occasion to express to his guest the gratitude of Havana and all Cuba for the efficient services rendered the city and island by the sanitary department, and especially for putting an end to the age-long endemic of yellow fever.

Oregon State Medical Society.—At the annual meeting of this society, held at Portland, September 10 and 11, the following officers were elected: *President*, Dr. Henry Waldo Coe, Portland; *Vice-Presidents*, Drs. F. W. Van Dyke, Grant's Pass, J. A. Geisendorffer, The Dalles, and J. P. Tamiesie, Hillsboro; *Secretary*, Dr. A. D. Mackenzie, Portland; *Treasurer*, Dr. Mae H. Cardwell, Portland.

A New Hospital for Portchester.—Many of the women of Portchester are interested in a project to erect a new hospital building there, in place of the old building which has harbored the patients since the Portchester Hospital was established a few years ago. The stone for the foundation has already been given, and a subscription list has been started with several substantial donations.

St. Mary's Hospital in Queen's Borough.—The medical staff of the new hospital in Jamaica, Queens Borough, to be known as St. Mary's, has been organized as follows: *President*, Dr. Philip M. Wood; *Vice-President*, Dr. George K. Meynen; *Secretary*, Dr. A. J. Blanchard; *Surgical Division*, Drs. Philip M. Wood, G. K. Meynen, A. J. Blanchard, and T. J. Flyn; *Medical Division*, Drs. H. M. Augur, Samuel D. Nutt, W. T. Scovil, and E. T. Jones; *Dental*, Dr. P. L. Hull; *Sanitary Department*, Dr. Samuel Hendrickson, Health Commissioner of Queens Borough.

The Climatic Cure of Consumption was the subject of the presidential address before the Medical Society of the Missouri Valley in its annual meeting at Sioux City, Iowa, on September 18. In it Dr. R. C. Moore of Omaha exposed some of the fallacies in the arguments for climate as a factor in the cure of tuberculosis, and contended that the open-air treatment of the disease could be carried out in Massachusetts practically as satisfactorily as in New Mexico. He advocated the establishment of local sanataria in every State of the Union.

Board of Health Licenses for Ambulance Surgeons.—The Assistant Sanitary Superintendent of the Board of Health in Brooklyn, Dr. Raymond, has notified the hospital authorities in that Borough that no one will be allowed to serve as ambulance surgeon until he has complied with the requirements of the Health Board. These requirements are that the surgeon shall be regularly qualified by the State Examining Board to practise medicine and surgery, and shall have had an experience of six months in private or hospital practice. The new regulation is to go into effect on the first of next month.

Obituary Notes.—Dr. THOMAS H. PHILLIPS of Canton, O., died suddenly at the desk in his office on Saturday evening, August 30. He was born at Cannonsburg, Pa., on March 25, 1839, and was graduated from the Jefferson Medical College, Philadelphia, in 1864. Before his graduation he served as an assistant surgeon in the Union Army during the Civil War. Dr. Phillips was the oldest practitioner in Canton; he was the family physician of the late President McKinley and had called professionally on Mrs. McKinley the day of his death. He was widely known as a consultant, and was a member of the Canton Medical Club, the Stark County Academy of Medicine, the Northeastern Ohio Medical Association, and the American Medical Association.

Dr. HARRY A. BELL, aged about thirty years, died in Tucson, Ariz., September 17. He was a graduate of Washington and Jefferson College and of the Medical Department of the University of Pennsylvania in 1897, and was a member of the Butler County (Pa.) Medical Society, the Pennsylvania State Medical Society, and the American Medical Association.

Dr. WALTER CURRY of this city died of acute pleurisy, at Brandford, Conn., on September 20. Dr. Curry was born in Lincoln, Ga., in 1835. He was educated at the University of Georgia, and was graduated, in 1855, from the Medical Department of the University of Pennsylvania. He served with distinction as a surgeon in the Confederate Army during the Civil War, and soon after its close came to New York to reside. Dr. Curry was a brother of Dr. J. L. M. Curry, who was sent by President Roosevelt as special envoy to Spain to represent this country at the coming of age of King Alfonso. He was the attending physician of the late William Marsh Rice for six months previous to the latter's death, and was to have been a witness in the new trial of Patrick, Mr. Rice's lawyer, in case he succeeded in getting one.

Dr. EDMUND HOWELL COOK of Flushing, L. I., died recently at the age of thirty-nine years. He was a son of Dr. Henry Cook of Sag Harbor, where he was born, and was a graduate of the Bellevue Hospital Medical College in the class of 1893.

Dr. CHARLES HENRY JOHNSON of Brooklyn died on September 18, at the age of forty-eight years. He was a graduate of the New York University Medical College in the close of 1880, and of the University of Dublin in 1881. He was attending physician to St. Mary's Hospital, and was a member of the Kings County Medical Society, the Brooklyn Pathological Society, the Brooklyn Medical Society, and the Associated Physicians of Long Island.

Dr. DANIEL L. WASSER died on September 19 in the West Penn Hospital, Pittsburg, from carbolic-acid poisoning, the drug having been given to him in an enema by mistake for olive oil. He was suffering from typhoid fever at the time.

Dr. FREDERICK G. IBACH of Mauch Chunk, Pa., died on September 11, at the age of forty-four years. He was a graduate of the Jefferson Medical College, Philadelphia, in the class of 1879.

Dr. CHARLES MERRITT, eighty-nine years old, died on September 21 at the home of his son, Dr. Charles G. Merritt of Mount Vernon. Dr. Merritt was a physician of Bridgeport, Conn., and had practised in that city for many years. He had been living at Mount Vernon only a short time.

The Care of the Perineum During Labor.—Effa V. Davis, during ten years of active obstetrical work, has used the following precautions to prevent rupture. All primiparæ and most multiparæ are placed in the left lateral position as soon as the presenting part has reached the pelvic floor, or begins to strain on the perineum. Chloroform is administered at the same time. Direct pressure is applied to the head when it appears at the vulva, but a slight advance is permitted at each contraction. Pressure applied to the jaw and lower part of the child's face by the fingers of the right hand carries the whole head snugly under the pubic arch and keeps the degree of extension or flexion just as desired to direct the occiput safely through the outlet, and allow the nape of the neck to lie under the pubis before the sinciput passes the perineum, which insures engagement of the outlet; not the occipito-frontal, which is much larger and apt to present when the above manipulations are not applied correctly. The author used to do episiotomy occasionally, but by practising the above measure this has been rendered unnecessary in the last 514 cases.—*Medicine*.

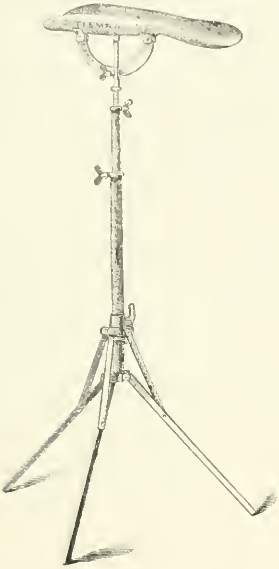
New Instruments.

A NEW ARM SUPPORT.

By F. S. KENNEDY, M.D.,
BROOKLYN, N. Y.

In a paper read before the Medical Society of the County of Kings, April, 1902, on "The Sphygmograph: Its Practical Value," particular attention was called to the necessity of having the forearm properly supported and steadied at the time of making a radial sphygmogram, in order to eliminate as much of the involuntary wrist movement and muscle tremor as possible.

At that time I was using an improvised arm-rest for this purpose which had a rotary motion and could be raised and lowered to suit each patient. Since then, at my request, Messrs. Geo. Tiemann & Co. have made for me an arm-support which not only rotates freely and can be raised and lowered but, by means of a hinged device with set-screw at the top of the supporting rod, it can be tilted from the horizontal so as to give a much greater degree of comfort to the patient.



A further advantage possessed by this support over the one first used by me is in the manner of fastening the sphygmograph to the wrist. When no support whatever is used, or when the forearm is made to rest on a book or table, and even with my first device, the band of the recording instrument is made to pass directly around the wrist, producing a degree of constriction which varies with each case, but always interfering more or less with the circulation. With this new support, however, both the hand and forearm are steadied, while the band of the sphygmograph, passing below the metal support at its narrowest part, does not constrict the wrist to any appreciable extent, and interference with the circulation is thereby avoided.

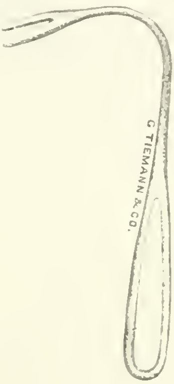
Aside from its use in conjunction with the sphygmograph, I have found this arm-support to be of great value, as part of my general office equipment, in cases of fracture, sprain, etc., when it is desirable that the arm and hand should be maintained in a steady and restful position during treatment, and while dressings are being prepared and applied.

The support includes a nickel-plated extension tripod, which can be so compactly folded that with the arm-rest it will make a package not more than sixteen or seventeen inches in length, and weighing less than thirty ounces.

A NEW TONGUE DEPRESSOR

By J. W. EDDY, M.D.,
OSWEGO, N. Y.

For a number of years I have been troubled in the removal of fish bones and other foreign bodies from the throat by patients gagging, and sometimes vomiting, which greatly interfered with the extraction. After experimenting with many different kinds of tongue depressors, I found that I obtained the best results with a uterine dilator with the blades spread. This holds the tongue down, and causes practically no gagging or vomiting. Hence my excuse in bringing before the medical profession a two-pronged tongue depressor, as shown in the accompanying illustration. It was made in a very satisfactory manner for me by Messrs. George Tiemann & Co. of New York City. This tongue-depressor is intended to be used only in operations for the extraction of foreign bodies.



Influence of the Light-Bath on the Circulatory Apparatus.—Ferdinando Battistini uses the light-bath according to Kellog's method, with forty lamps rendered incandescent, by a current of 100 to 110 volts. He begins with a temperature of 30°C., progressively increasing up to 50°, and rarely to 60° C. The duration of the bath is from fifteen to twenty minutes. In all cases copious sweating occurs promptly. The pulse and the respiration are increased in frequency. The effect on the blood-pressure varies. In persons whose circulation was normal, or in whom arteriosclerosis was in the initial stage, the pressure was very slightly increased, or else not affected. In a second group of patients, apparently normal or else suffering from grave arteriosclerosis, the pressure was as high as 35-60-70 mm of mercury. Arrhythmia was noticed in some cases. The cardiac area was, as a rule, not affected. The sphygmographic curve was usually fuller during the light-bath and occasionally there were signs of dicrotism. The author concludes that this method of treatment should be used very cautiously on patients with a weak heart, or on those suffering from arteriosclerosis.—*Rivista Critica di Clinica Medica.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

A MUNIFICENT ENDOWMENT—CONGRESSES—WORKMEN CLAIM TO ELECT THEIR DOCTOR—MR. CHAMBERLAIN ON THE AMBULANCE CORPS—DR. T. W. LAW—SIR V. HORSLEY'S SEAT ON G. M. C. STAFF COLLEGE—BOOKS—THE LATE MR. COLEMAN.

LONDON, September 5, 1902.

THE King seems to have a fair chance of seeing his wish about our London hospitals accomplished. On Wednesday it was announced in the newspapers that the Prince of Wales, as President of the Executive Committee of King Edward's Hospital Fund for London, had received from Lord Mount Stephen and Lord Strathcona an endowment for the fund producing £16,000 a year and likely to increase in value.

When as Prince of Wales in 1897, the King established this fund, he hoped to free our hospitals from the heavy debts which burden them, and it was thought that £100,000 a year would be required to accomplish this. The Prince hopes to see this end attained in this year, the first of his Royal Highness's Presidency.

For my part I hope that the prospect before them will not tempt managers into fresh extravagances. It would be well if it were understood that hospitals incurring fresh debt would have to justify their action fully to the committee or be struck off the list of beneficiaries. Secretaries and architects seem always ready to rush into debt, and some, it is well known, believe that a heavy debt constitutes the most effectual appeal to the public. This notion should be sternly repressed. There are other directions, too, in which managers are apt to be reckless, and their ambitions will have to be curbed.

This is the season of congresses and conferences. You may feel some interest in that of the journalists. Their institute has discussed the position of proprietors, managers, editors, art-critics, etc. A voice was also raised in favor of making it international, but the objections were obvious, and reference to continental abuse raised the cry of "no politics." I think the journalists would be better advised if they set their faces against the shameful advertisements which circulate in their papers. The *Daily Telegraph* does not blush to accept a whole page advertisement of a so-called institute for the cure of deafness which has been over and over again exposed as a gross swindle. Other dailies, too, insert advertisements which are a disgrace to them.

The Trades' Union Congress has also been inflicting its proceedings upon us, and a number of people have been startled by the demands of some of the speakers. Workingmen, they think, should rule the country through the trades' unions. Non-unionists must join them or be crushed out; picketing must be legalized for this purpose, and, of course, intimidation To free education must be added free technical schools, to teach their trades, and then free meals. Rehousing on the largest scale is demanded at minimum rents, and pensions for those who reach the age of sixty. To do all this the trades' unionists propose to form themselves into a great political party, stronger than either of the existing parties, to reconstitute the House of Commons, and for funds to tax land to its full value, and, to municipalize or nationalize many other forms of property—a program of confiscation and revolution.

Though not mentioned at the Congress, we all know that the workman has long ago secured free medical treatment, and considers that he has a right to a share in the management of hospitals founded and supported by others.

A number of our surgical brethren have accepted invitations to be present at the Belgian Surgical Congress. Appendicitis is again a leading subject for discussion. Lord Lister was invited, but is unable to go.

The name Ballachulish may have caught your eye in some cable about the King's cruise. The place is noted for its slate quarries, in connection with which a remarkable dispute has arisen. The company owning the quarries recently dismissed the medical officer at a month's notice and forbade him to practise in the district in accordance with a clause in the agreement. The quarrymen, as soon as they heard of it, called a meeting and passed a resolution asking the directors to reconsider their action. This they declined to do, and at another meeting the quarrymen resolved to make every effort to retain the services of their medical officer (Dr. Grant), and appointed nine of their number to act as a medical committee to secure this end The directors, still persisting in their decision, this medical committee resolved to assume the right of appointing their own officer, and gave notice that they would not allow deductions from their wages on behalf of any doctor they had not themselves appointed. Notice was served on Dr. Grant that the court was to be asked to interdict him from practising in Ballachulish, and an indignation meeting of the men followed, so numerously attended that it had to be adjourned from the Town Hall to the open air. This meeting resolved to use every legitimate means to retain the services of Dr. Grant and to employ every legal means of preventing deductions being made from their wages for the payment of any other doctor.

Some people think there ought to be arbitration instead of litigation. I think it would be more reasonable for the directors to retire from their ridiculous position, and, as the doctor is paid by the men, let them choose him. Surely Scotchman know their proverb that "He who pays the piper calls the tune."

Sir Wm. Church, P.R.C.P., presided at the meeting of subscribers to the fund raised by sympathizers with Dr. T. W. Law. You will remember that he was prosecuted by a nurse, to whom he had been most kind, in attending her gratuitously, the charge being that through his treatment she became addicted to morphine. The jury stopped the case before hearing all the defence, and the judge declared the action ought not to have been brought. But the grateful nurse had no funds to pay the costs, which ran up to about £700. Sir W. Church handed Dr. Law a cheque for £500. He had previously received £110 from the fund. Dr. Law expressed his thanks to the profession for its generous assistance.

Some good speeches were made and resolutions passed. The case illustrates, as I said at a previous stage, the value of a medical defence fund. Probably, had Dr. Law belonged to one of the protection associations, he would not have been subjected to the ordeal he has gone through.

Sir Victor Horsley's term on the General Medical Council is expiring. He is a candidate for re-election, and his services ought to give him an unopposed return. There is some talk of opposition, but I hope it will end in talk. As nomination papers may be sent in to-day, I cannot say positively whether this will prove to be the case.

Forty members of the Birmingham corps of the St. John Ambulance Brigade, who served with the R. A. M. C. in South Africa, received war medals on Saturday at the hands of Mrs. Chamberlain, and were addressed by the Colonial Secretary himself. He expressed his appreciation of their services in handsome terms, and said that combating the terrible diseases, which were more fatal in war than sword or bullet, was quite as honorable as fighting with other weapons. In glorifying such voluntary work, however, he said the country would not submit to the expenditure necessary to be always ready for any emergency—a statement which his enemies are making the most of and which has filled his supporters with apprehension and even consternation.

The new Army Medical Staff College has begun its first session in the laboratories of the two colleges, which the War Office has hired for the purpose. Lieutenant-Colonel H. E R. James of the Aldershot Training School R. A. M. C., has been appointed commandant and director of studies.

A book entitled "Rich and Poor in the New Testament," by Dr. O. Gone, was published on Wednesday. The author calls it a study of primitive Christian doctrine, which he endeavors to apply to our present social state.

A volume of surgical contributions by the late Sir Wm. Stokes is announced for next month. Sir William had begun their revision when he offered his services for South Africa. The work will be edited by Mr. Taylor of the Meath Hospital, and Professor Ogston will contribute a sketch of the author's life.

A rather cheap edition (3s. 6d.) of Treves's "Tale of a Field Hospital" has already appeared.

The first volume of "Reports from the Cancer Research Laboratories; the Middlesex Hospital," has appeared. It is edited by Mr. Foulerton.

Mr. Alfred Coleman, F.R.C.S., L.D.S., etc., died on the 26th ult. He was an original member of the Odontological Society, of which he was President in 1877. He had taught at the Dental Hospital and examined at the College of Surgeons, and long held a leading position in dental science and practice, to which he was most devoted. You will remember his "Manual of Dental Surgery and Pathology" and some of his contributions to the journals. His health failing, he went to New Zealand, where he stayed from 1884 to 1890. On his return he occupied himself with his old hospitals' management—St. Bartholomew's, of which he was for many years dental surgeon.

NASOPHARYNGEAL CATARRH.

To the Editor of the Medical Record:

Sir: I have been interested in an article, published in your issue of August 9, by Dr. Freudenthal, on the subject of chronic nasopharyngeal catarrh. The author ascribes this disease to the dry atmosphere in which the American passes the principal part of his life. He says that the rooms of American houses are nothing else but cave-dwellings, tighty closed from all sides during the greater part of the year. I do not deny the unhealthy consequences of living in such houses, but I cannot agree with my colleague in considering such a practice as the principal cause of the high percentage of pharyngeal catarrh amongst people living in America.

How can Dr. Freudenthal explain the fact that foreigners, coming to America, living as they do at home, with plenty of fresh air and very little fire, and some of them also living an outdoor life, are affected, after a certain time, with the same trouble. For over a year I have paid particular attention to this fact here in Washington, where the foreign colony is numerous, and represented by all nationalities, and I have arrived at a very different conclusion.

Americans appear to be unable to dispense with drinking ice-water; foreigners also acquire, almost unwillingly, the habit—and why? Because the hotels, restaurants, boarding-houses, business places, from the Stock Exchange to the smallest retail shop, supply the customer with a pleasant drink of ice-water at any hour of day or night. Of course, I am willing to admit that if our dwellings, in all season, were not so stuffy, because of excessive heat, the ice-water would not have such an attraction. Our nasal and pharyngeal mucous membranes, as my colleague says, are, in consequence of the overheated atmosphere, kept dry and hot, and, I may add, for that reason, in continuous need of refreshing drinks. That is true, but what we must take into consideration is the effect of the abuse of ice-water on our system. In the beginning ice-water stimulates the action, *e. g.* the secretion of the gastric glandular apparatus. This stimulation, after a certain period, has, on the stomach, the same effect that all stimulants have on it. The excess of alcohol, the excess of spicy foods, or the action of the extreme temperatures, either too hot or too cold, of the food injested, produce a chronic catarrhal condition of the stomach.

The pharynx is nothing else but an intrinsic part of the gastric apparatus; and we know that any process of an inflammatory character has a tendency to extend itself *ad infinitum* over surfaces not separated by well-defined lines of demarcation, viz., lines representing the starting points of radical histological differentiation. So to a catarrh of the stomach always follows a catarrh of the pharynx. It is an axiom that clinical daily observations demonstrate and pathology confirms. Once this catarrhal condition is started in the pharynx, we have there a ground of culture for the numerous colonies of microorganisms living in the mouth. These flourishing colonies will gradually invade the retropharynx, and from there all the surrounding regions, giving rise to all the catarrhal conditions and complications that constitute the greater part of otorhinological pathology. In other words, the nasopharyngeal catarrh forms part of the multiform pathology of dyspepsia. If Dr. Freudenthal would make statistics of all the cases of nasopharyngeal catarrh under his observation, I do not doubt he would, in every case, find marked signs of dyspepsia.

I had many occasions, during last winter, to observe and treat such cases. The recent ones, in which distrophias had not yet begun, I always successfully treated in the following way: (1) Regimen proper to a dyspeptic person; (2) Complete abstinence from ice-water, in all forms: (3) Frequent gargles of the following solution:

Sodii boratis Sodii bromidi	āā 6 gram.
Acidi carbolici	1 gram.
Glycerini	50 grams.
Aquæ rosæ	450 grams.

The patient always improves rapidly. I should advise the practitioner to undertake the above treatment in cases of this character.

Enrico Castelli, M.D.

1518 K Street, Washington, D. C.

The Harlem Medical Association.—At a meeting held on June 4, officers for the enusing year were elected as follows: *President*, Dr. E. L. Cocks; *Vice-President*, Dr. W. H. Luckett; *Secretary*, Dr. Percy Fridenberg; *Treasurer*, Dr. J. L. Feinberg; *Trustees*, Drs. J. E. Lumbard, M. R. Richard, and Henry Hemian.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Sept. 18, 1902.

Notes on a Case of Acute Hemorrhagic Polymyositis.—William Sydney Thayer says that it is only within the last fifteen years that our attention has been called to the various forms of acute polymyositis apart from that occurring with trichinosis. The essential features of the case he reports appear to have been recurrent attacks of acute swelling, with but little tenderness, in various muscle groups. The more severe attacks have been associated with evidences of deep hemorrhage (widespread discoloration of the skin) and areas of marked hard subcutaneous œdema. During one of the attacks there was a deep, almost erysipelatoid, reddening of the skin in the œdematous area. Subsequently there were undoubted evidences of atrophy in some of the affected muscles. Certain points of especial interest in the course of the case were: (1) The mildness of the subjective symptoms of pain; (2) The mildness of the febrile manifestations; (3) Widespread cutaneous discoloration, indicative of deep hemorrhage, almost without purpuric manifestations; (4) Crepitus in the deltoid muscle.

The Effects of Exercise on the Heart and Circulation.—R. C. Larrabee summarizes his paper as follows: Violent exertion normally causes changes in the blood pressure, temporary enlargement of the heart's area from dilatation or relaxation of the myocardium, and sometimes a fugitive murmur. The cause of the latter is not obvious. The chief result of training is hypertrophy. As abnormal results of exercise we have acute dilatation, rare in healthy young men, especially if well trained; and as a result of habitual overexercise, "irritable heart," and the other conditions with dilatation, hypertrophy, or myocarditis, and generally due in part to other predisposing causes. In the treatment, rest is of the first importance, its duration and degree depending on the severity of the case. The diet should be abundant and nourishing. Digitalis and other cardiac stimulants are of the greatest value, but they should be given, especially at first, with great care, their action being closely watched. In the prophylaxis, careful training is important. Excesses in the use of tobacco and alcohol should be especially avoided by those whose occupations require unusual muscular exertion.

Journal of the American Medical Association, Sept. 20, 1902.

Analysis of Thirty-seven Cases of Uveitis.—This analysis is made by Hiram Woods, who summarizes his views as follows: (1) Menstruation in its establishment or later, if abnormal, intestinal disorders, acute infections, and nasopharyngeal disease should be reckoned among possible causes of plastic choroiditis. Whether or not these conditions are themselves direct causes or lower resisting powers, and so enable other causes to act, is uncertain. Nor can it be definitely said that some of these coincident conditions may not themselves be manifestations of recognized causes of uveitis; rheumatism, anæmia, and the like. (2) These cases of obscure etiology show greater tendency to relapse than forms whose cause is better known. They almost invariably show descemetitis. (3) The fundal changes of so-called "choroidal hyperæmia," especially if accompanied by defective accommodation and vitreous opacities, demand guarded prognosis and repeated examination for dim field areas.

Concerning the Symptomatology and Etiology of Certain Types of Uveitis.—G. E. de Schweinitz describes cases illustrative of the following types of the disease: (1) Recurring and malignant uveitis terminating in secondary glaucoma and cataract; (2) Acute uveitis, beginning as a scleroticochoroiditis, terminating in myopia and posterior polar lenticular opacity; (3) Mild, chronic, senile uveitis, associated with antecedent or subsequent hemorrhages in the vitreous, and (4) Relapsing, plastic uveitis, beginning insidiously in gouty and rheumatic subjects. In general terms, the causes of the disease may be diathetic, toxic, or infectious. Thus, we have causes depending on rheumatism, gout, and diabetes; on specific infections, such as influenza, syphilis, gonorrhœa, tuberculosis, and specific fevers; blood states, as anæmia; on urinary anomalies, as lithæmia, and on local diseases, *e. g.* of the pelvis and rhinopharynx. In what manner these various ailments and conditions cause iridocyclitis, or, to use the more comprehensive term, uveitis, has not been carefully determined. But it does not seem to be unreasonable to assume that it represents an effort on the part of the uveal tract to expel from its tissues some toxin, bacterial or otherwise, precisely as we know that certain forms of dermatitis originate in an effort of the skin to eliminate a poisonous agent. Under each of the four headings mentioned above are grouped the characteristic symptoms and conditions found in the corresponding type of case.

Medical News, September 20, 1902.

Report of a Case of Non-Traumatic Acute Suppurative Osteomyelitis with Catarrhal Coxitis; with Remarks.—Henry J. Raymond, in discussing this subject, enumerates the following symptoms: A sudden invasion—a child takes to bed from the first day—fever and chilly sensations and a complete abolition of functions of the affected limb, with terrific spontaneous pains in the hip or knee. Pressure over the trochanter, or striking the soles of the feet, and any attempt at passive movement of the limbs, increase the pains. (In tuberculous coxitis the onset is not sudden.) Swelling about the hips, the gluteal, and anterior femoral regions, of a boggy œdematous character, sets in. There may be multiple joint affections, as in rheumatism. In some one joint the inflammation becomes localized, while the other affected joints clear up. The catarrhal cases may clear up in from four to six months, or possibly a year; the suppurative cases may continue for three or four years should the patient not succumb to pyæmia, septicæmia, or some intercurrent affection or amyloid degeneration of organs. Spontaneous luxation of the joint may ensue, with ankylosis and distortions; namely, flexion, adduction, abduction, rotation, or combinations of these.

The Influence of the Röntgen Ray upon the Different Varieties of Sarcoma.—William B. Coley concludes that although the present series of cases is too small, and the time of observation too short, to justify one in drawing any dogmatic conclusions as to the permanent therapeutic value of the Röntgen ray in sarcoma, we are still warranted in stating: (1) That the results in the cases thus far treated prove that the Rontgen ray has a remarkable inhibitory action upon the growth of all forms of malignant disease, and that this is especially true of sarcoma; (2) That this action in many cases of even far-advanced and inoperable malignant disease may result in the total disappearance of the tumors, often without any breaking down of the tissues, the new growth being apparently absorbed; (3) Whether the patients have been cured, or the disease has been merely arrested, to reappear at some future date, is a question that time alone can decide; (4) Recent observations and experiments upon the various forms of carcinoma and sarcoma prove that an agent supposed to be of value only in a very limited class of superficial epitheliomas promises to be of as great or even greater value in practically every variety of cancer; (5) While at present there is little evidence to show that deep-seated tumors in the abdomen and pelvis can be cured or benefited by the Röntgen ray, there is still some reason to hope that, with improved apparatus, or with greater knowledge and skill in using the apparatus than we now have, even these cases may be benefited; (6) The Rontgen ray has a very marked influence upon the pain of nearly all types of malignant tumors, causing entire relief in the majority of cases.

New York Medical Journal, September 20, 1902.

The Radical Treatment of Cancer of the Penis.—E. W. Lee thus describes his favorite operation: The patient is placed in the lithotomy position, the pendent portion of the penis is wrapped in wet carbolized gauze and covered with rubber tissue. The organ is transfixed as near the base as possible with two short needles; under these should be placed a rubber band, and the pendent portion of the organ is amputated by a transverse incision. The skin of the scrotum is then incised along the whole length of the raphe; with the finger, and the handle of a scalpel, the scrotum is separated into halves quite down to the corpus spongiosum; a full-sized metal catheter is now passed into the urethra, as far as the triangular ligament. In passing the catheter it will be necessary to partly remove the rubber band, which has been placed at the root of the penis. A knife is now inserted transversely between the corpora cavernosa and the corpus spongiosum; the catheter having been withdrawn, the urethra is cut across, and the deep end of the urethra is then detached from the penis quite back to the triangular ligament. An incision is then made around the root of the penis continuous with that in the median line; the suspensory ligament is divided and the penis is separated, except at the attachment of the crura. The knife is now laid aside, and with a stout periosteal elevator each crus is detached from the pubic arch. This step of the operation involves some length of time, on account of the very firm union of the parts to be severed. Four arteries require ligature—the two arteries of the corpora cavernosa and the two dorsal arteries. The corpus spongiosum is slit up for about half an inch, and the edges of the divided urethra are stitched to the back part of the incision in the perinæum. The scrotal incision is then closed with sutures, and a drainage tube is inserted so far back in the deep part of the wound that it can be brought out in front and behind. No catheter is retained in the uretha.

The Plague; Its "Diffusive Tendency"; Haffkine's Antiplague Virus vs. Yersin's Serum.—J. D. Burch gives a brief summary of the history of the epidemics of the plague, and illustrates his paper with excellent views of Haffkine's laboratories in India. His article is, in a sense, a polemic one, his opinion inclining toward the superiority of Haffkine's remedy over that of Yersin. He bases this opinion on the various reports put forth regarding the relative value of the two, reports based upon actual clinical experiments. The current opinion has been that the Haffkine material should be used as a preventive on persons before their exposure, while the Yersin treatment may be used either before or after exposure, or while a person is suffering from the disease. The Yersin remedy has been exploited by Calmette, who reported, in 1900, that a person in the period of incubation for a slight attack of the plague would find the disease considerably aggravated if he submitted during this period to preventive inoculation of Haffkine vaccine. The reply to this statement is, according to Burch, to be found in the report of Major Bannerman of the English army, who says that as Haffkine, on the contrary, has all along maintained that inoculation with his vaccine is harmless in the incubation period of plague, and that this method of protection should be pushed with the utmost vigor amongst those immediately in contact with plague cases, it becomes necessary to examine this matter afresh, in the light of the extensive experience gained in India and elsewhere in the use of the plague prophylactic. Calmette's ideas have been derived from laboratory experiments, for he has had no opportunity of studying the effect of plague vaccination during an epidemic of human beings. In India, on the contrary, hundreds of thousands of persons have been inoculated with Haffkine's plague vaccine, and evidence has been now accumulated with sufficient accuracy to enable one to refute entirely the above suppositions of Calmette.

American Medicine, September 20, 1902.

The Excision of Cancer of the Rectum.—Lewis H. Adler, Jr., believes that cancer of the rectum, at the stage usually discovered by the surgeon, is less amenable to the knife than cancer occurring in other parts of the body; that operation is followed by cure in a very small proportion of cases; that the dangers following excision are great, and the results as to comfort anything but satisfactory; and yet, that in properly-selected cases—those seen early—much good can be accomplished by the operation. The writer wishes to open up the subject for discussion, so that the most recent individual experience and opinion regarding the merits and demerits of excision, as well as its limitations and indications, may be learned.

The Differential Leucocyte Count in the New-born.—Louis M. Warfield concludes that: (1) The leucocytes at the day of birth are more numerous than at any other time of normal life. (2) Nucleated red blood corpuscles rapidly disappear from the circulating blood of the healthy infant within the first three days of life. (3) The percentage of eosinophiles varies widely in the blood of babies of the same age. (4) Myelocytes and mast cells are only occasionally found, and are in very small numbers. (5) The percentage of large mononuclear and transitional cells is large compared to that found in the blood of adults. (6) The polymorphonuclear cells at birth are not only relatively but absolutely increased. They begin to decrease in numbers soon after birth, and by the eleventh day of a healthy infant's life they are fewer in number than the lymphocytes, while the number of the latter variety of cell has actually increased; and the differential count of the leucocytes on the eleventh day is practically identical with the count given in the text-books as normal for the infant's blood.

The Rational Basis for the Dietetic Treatment of Tuberculosis.—William Henry Porter gives the following as the natural deductions to be drawn from his study of the dietetics of tuberculosis: (1) A predisposition to tuberculosis is inherited. (2) Tuberculosis *per se* is never inherited, but is always acquired after birth. (3) The disease can be fed into or fed out of the human species. (4) The chief problem in the dietetic treatment of tuberculosis is first to overcome the general malnutrition, and next to establish a higher grade of local nutrition at the infected focuses. (5) The composition, digestibility, and percentage absorption of the various foodstuffs and the oxygenating capacity of the system is accurately known. (6) By this knowledge the quantity of food taken can be accurately adjusted, so that the full heat production and constructive utilization of the proteids is secured. (7) The oxygenating and carbon dioxid excreting powers of the system must not be exceeded if the best results are to be secured. (8) By following these accurate laws systematically, a perfect diet can be arranged, and the abnormal and pathologic conditions can be changed to the normal, physiologically speaking. (9) The most difficult problem to contend with in the dietetic management of tuberculosis, is the loss of appetite and the inability on the part of the system to digest and utilize perfectly a sufficient quantity of proteid material to maintain life, and, at the same time, repair the damage already wrought. (10) When this is accomplished a large percentage of tuberculous patients are rapidly and permanently cured, more so than by medicinal treatment or simple climatic changes. (11) A universal adherence to these laws through a century might result in a complete eradication of tuberculosis from the human species.

Two Aneurysms in a Single Heart.—L. M. Loeb describes this case. The patient was a negro porter, twenty-six years of age. He had been entirely well till within three weeks before his arrival at the hospital. He had at that time "taken cold" and his condition became progressively worse. He coughed, but expectorated no blood. There was marked dyspnœa, relieved by sitting up, but not by lying down, and increased by exertion. He had "palpitation of the heart" for about three weeks, and a sharp pain ran from the cardiac region to the left shoulder. The apex beat of the heart was seen and felt in the seventh interspace in the left midaxillary line. It was equally distinct over an area of about one inch in diameter. The seventh and eighth ribs were further apart at this place than elsewhere. Dulness began in the second interspace to the left of the sternum, and passed downward and outward to the eighth rib in the midaxillary line. It extended just beyond the right border of the sternum. This area of dulness shifted $\frac{3}{4}$ of an inch to the right or left as the patient turned on the corresponding side. Over the apex the tones were muffled, in spite of the forcible pulsation. In the second left interspace the second sound was accentuated. In the second right interspace was a loud, blowing, diastolic murmur, not transmitted far in any direction. The temperature remained subnormal. The dyspnœa increased, and the expectoration became quite bloody. Autopsy revealed a dilatation aneurysm of the left auricle at the apex, and a dissecting aneurysm of the aorta leading into the wall of the left ventricle. There was fibrous obliterative pericarditis. The heart with the pericardium and the beginning of the great vessels weighed nearly 1,000 grams. The diagnosis of the condition was hardly possible, although the aneurysm at the apex was once suggested on account of the marked bulging in the seventh interspace. The history was suspicious of syphilis. The writer believes the following may have been the sequence of anatomic changes in the present case: (1) The adhesive pericarditis produced the enormous hypertrophy of the heart. This gave rise to a blood-pressure which the sclerotic aorta could not withstand, and the aneurysm at the base resulted. The possibility of the perforation of a so-called atheromatous ulcer should be considered. This aneurysm pressed upon the left coronary artery, and in this way interfered with the chief source of blood-supply for the apex, and the tugging of the diaphragm, and greatly increased blood pressure in addition, were sufficient to cause the second aneurysm

Philadelphia Medical Journal, September 20, 1902.

Medical Representation in Hospital Management.—Augustus A. Eshner states that there are several ways in which satisfactory representation can be given the medical staff on the board of management of a hospital: 1. By electing one or more members of the staff to membership on the board. 2. By periodic conferences between the staff and the board. 3. By conferences between a committee of the staff and the board or a committee of the board. There is a common theory that the physician is unsuited by inclination, temperament and ability for business activity, so that he is sometimes excluded from taking part in those business affairs for which he should be, and generally is, most eminently fitted and qualified. Certain lay boards of hospital management have allowed the opinion to become common that hospital management is a purely business matter, and that the medical officers should be considered as mere subordinates, to receive and fulfill the orders of their superiors, the lay managers. The physician is, however, on account of his training, his attainments, his position and his relations with others, especially fitted for this work of which some have judged him incapable. Neither the hospital staff nor the medical staff should be subordinate, but they should work together, and each should supplement and complement the work of the other, so that the efforts of each will be strengthened in their mutual coöperation. There are questions arising many times in a hospital in which the advice of the physician is absolutely necessary. The successful management of a hospital, therefore, will be attained by a division of labor, such as assigns purely business responsibility to the lay managers, and all purely professional work to the medical staff. There should be entire harmony between the two divisions.

Syphilitic Necrosis of the Nasal Cavity, Accompanied with Total Blindness.—Charles A. Todd describes this case of syphilitic disease of the nasal cavity as one of interest outside of rhinology on account of its ophthalmic complication. The patient was a man aged forty-seven. There was almost complete destruction of the nasal septum and at the same time complete blindness. The cavity of the nose was syringed with an alkaline solution and from time to time pieces of dead bone were removed. The use of the antiseptic washes was followed by the application of vaseline on a swab. The fetor rapidly disappeared. At later visits, it was found that nearly all the septum was gone. The vault of the pharynx was intact, and the anterior part of the body of the sphenoid was unhurt. The eye affection then could not be referred to extension of the necrosis. The sight began to grow dim three weeks previous to the patient's first visit There was a jerking headache in the right temple He was put on potassium iodide and the protiodide of mercury. The sight of the eyes is improving. The mucous membrane of the nose is well healed. The alkaline antiseptic wash and vaseline are continued. At the onset of the treatment there was some atrophy of the discs but no other intraocular lesion There was marked diminution of the field of vision and power of central vision. There was at no time any involvement of other cranial nerves beyond what the headache in the right temporal region might indicate.

The Lancet, September 13, 1902

A Method of Treating Traumatic Tetanus. The plan suggested by S. Zlotowski consists in keeping the patient in a room at a temperature of about 104° to 111° F., and giving him, every three hours, a hot bath of thirty minutes' duration. Morphine injections are made along the vertebral column for the relief of pain. Several illustrative cases are recorded.

Two Cases of Foreign Bodies Swallowed and Their Treatment.—H. W. Boreham records the cases, one being that of a woman who had swallowed a tooth plate, and the other that of a man who had swallowed a pin. He gave one dose of ammonium bromide (20 grs.), and then placed the patients on a diet of bran and coarse porridge, with small pieces of thread in large quantities. In both instances the bodies were safely voided in two days. He advises a restricted use of fluids during the treatment, and the confining of the bowels somewhat by the use of opium.

The Choice of an Anæsthetic for Short Operations upon the Throat and Nose.—The paper of J. H. Chaldecott is a vigorous protest against the use of chloroform for the purpose suggested in his title He shows that since 1897 at least *thirty* deaths from chloroform have been recorded in adenoid operations alone. He prefers gas alone, or gas and ether, and emphasizes the following points: (1) Chloroform has been the means of destroying more than fifty lives during adenoid operations, and cannot, therefore, be regarded as other than a dangerous anæsthetic in this class of cases; (2) At least five of these deaths have occurred in the practice of anæsthetists of the highest possible skill and experience; and (3) Thousands of these operations are performed every year under gas, or gas and ether, without a single death and with hardly an anxious moment.

A Case of Hæmophilia in a Woman with Symptoms of Defective Circulation in the Legs and Threatened Gangrene of the Toes; Death with Cerebral Symptoms. J. A. Arkwright reports the case, his patient being a tall, large-boned, and well-developed woman, who, at the time of her death, was thirty years old. The symptoms of her final illness came on without apparent cause, and are thus commented on by the author: The tendency to bleeding was shared by a brother, and though not extreme, and not traced to a former generation, it resembled hæmophilia The coldness and deficient blood supply to the lower limbs had some resemblance to Raynaud's disease, but the symptoms were too persistent and progressive and did not intermit with sufficient completeness to agree with the classical description of that disease. Moreover, the symmetry was very imperfect Exacerbations were generally excited by the use or dependent position of the legs, and were not truly paroxysmal The mottling of the skin affected the lower limbs high up, and even the buttocks, and consequently the circulation must have been defective in these parts This suggests some obstruction to the main arteries of the limbs, but the arteries supplying the feet were also not all felt beating in the usual situations. An arteritis, or constriction of the smaller arteries possibly due to nervous influence, seems to be the most likely explanation of the symptoms, but this leaves the ultimate cause and the connection with the tendency to hemorrhages unaccounted for. Perhaps the neuralgic pains in the limbs were due to deficient blood supply or deep hemorrhages. The final cerebral symptoms preceding death are best explained by meningeal hemorrhage, determined by the increased blood pressure preceding the menstrual period, but intracranial hemorrhage does not appear to be a recognized cause of death in hæmophilia.

The Ultimate Results in a Series of Seventy-six Cases of Fractures of the Tibia and Fibula.—R. W. Murray deplores the lack of progress made in the treatment of simple fractures, and notes that the usual treatment in England, at least for fractures of the tibia and fibula, that of placing the limb in a back-splint with a vertical footpiece and side-splints, is not the most advisable plan to follow. He prefers a footpiece inclined outward to an angle of seventy degrees, and with the same inclination forward. A splint so shaped permits of the foot and leg being fixed in the natural position of rest. The patient is more comfortable in a splint of this description, and as no endeavor is made to force the foot into an unnatural vertical position, there is much less tendency to the formation of a sore over the heel. Moreover, the tendo-achillis not being in a state of passive tension (as is the case when the vertical footpiece is used), the tendency to overriding of the fragments is lessened. The legpiece of this splint should be of such a length as to permit of the knee being bent, and, after the applications of side splints, to allow the leg and splint to be swung from a cradle. When the fractured bone has firmly united, say at the end of four weeks, movements of the ankle and knee-joints should be encouraged, and massage practised if available. The mistake usually made is keeping the injured limb in a state of immobility for too long a time. If the fracture has been an oblique one, it should be remembered that the newly-formed callus will have to bear the strain of the body weight, and consequently will be apt to "give" if the patient rests the full weight of his body on the injured limb before the end of the third month. The *x*-ray shows that with any form of splint it is often difficult to secure exact apposition of the broken bones, and he does not hesitate to operate in cases of simple fracture if necessary to secure accurate apposition. He notes that in compound fracture the results are often better than in simple fracture, owing, doubtless, to the fact that the wound relieves the soft parts of extravasated blood and inflammatory products.

The British Medical Journal, September 13, 1902.

Cannabis Indica in Chorea and Pertussis.—E. T. Burton describes several cases in which he has used cannabis indica with great success. In an aggravated case of chorea in a girl of eleven years, after other drugs had been tried without success, he administered seven and one-half minims of the tincture of the fluid extract. The effect was magical. In a few weeks the child became strong and well. In two cases of pertussis, one that of a boy of twenty-two months, and the other a girl of five years, the results were just as encouraging. Although the boy had suffered from an almost incessant cough with vomitting, the cough had almost ceased on the third day, and had disappeared by the end of the week. In all three cases there was noted direct relief to spasm, absence of any head symptoms, and non-interference with appetite or digestion. Only a little chloroform was added to the tincture to conceal the slightly unpleasant taste. The mixture was well taken in each case.

Note on a Case of Mammary Abscess Following Typhoid Fever.—Alfred MacConkey reports this case. The patient had an attack of typhoid fever in August of 1901. At the beginning of the following February she developed in the right breast a small painful swelling, which increased in size and finally burst Some of the discharge was examined. It was a thin, blood-stained, seropurubent fluid full of bacilli. In a dilution one in thirty it gave complete agglutinative reaction with the laboratory typhoid culture. Gelatine plates yielded a pure culture of a bacillus which gave all the cultural reactions of the bacillus typhosus. A guinea-pig, inoculated with a 48-hour broth culture of this organism, died in twenty-four hours. The bacillus was recovered from the spleen, and acted toward enteric blood just in the same way as the laboratory stock culture Later, the blood of the patient in a dilution one in thirty had only a partial effect upon the bacillus isolated from the discharge. The discharge itself, on the other hand, in similar dilution, gave a complete serum reaction with both the bacillus isolated from the abscess, and the stock bacillus typhosus. No information could be obtained as to the previous agglutinative power of the blood

Germ Infection in Tuberculosis. George Ogilvie calls special attention to the experiments which have been performed by Dr. F. Friedman. He put doe rabbits with bucks immediately, or, at the latest, a few hours after delivery. This he believes is the only period at which, in rodents, and in rabbits particularly, copulation leads with certainty to conception and gravidity. Directly after coition one or two drops of a thin emulsion of tubercle bacilli in a sterile and slightly alkaline solution of hydrochlorate of soda were injected into the vagina. On examining, about an hour later, the mucous gathering at the exterior mouth of the womb, large quantities of spermatozoa were found and only isolated tubercle bacilli. The female rabbits were killed within a week after the performance of the experiment. In all the embryos tubercle bacilli were found. Their number varied considerably with different mothers, and also with different embryos of the same mother. It is remarkable that the number of places in which the tubercle bacilli were found vary in different individuals belonging to the same pregnancy from two in one to twenty-six in another. Not a single tubercle bacillus was found by microscopical examination of the mucous membrane of the uterus or the vagina. In the open lumen of the uterus twice only an isolated bacillus was detected in close neighborhood of the embryo. Of course, no pathological changes of the maternal organs due to the tubercle bacillus could be expected in so short a period, but there was every reason to expect numerous tubercle bacilli in the open lumen of the uterus, or, at least, adjacent to the mucous membranes of uterus and vagina. This is not the case, however, and it seems that all bacilli which do not make their way into the ova are eliminated from the genital tract. The mode by which the bacilli reach the female cell has not yet been discovered. How the bacilli develop in the embryo, at what time the first anatomical and histological signs of tuberculosis become apparent, and whether the mother remains healthy or becomes infected, remain yet to be demonstrated. It will also have to be shown in embryos at the earliest stages before the formation of a placenta that males rendered tuberculous by injection produce infected offspring, while the mother remains immune. The experiments which have been made in this field seem to prove that tubercle bacilli introduced into the vagina, together with the semen, may pass into the embryo without the intermediary of a mother. It is a question altogether different how frequently, if at all, this takes place in human tuberculosis. On this point nothing is known.

Deutsche medicinische Wochenschrift, August 28, 1902.

Number of Leucocytes in the Blood During Pregnancy, Labor, and the Puerperium.—W. Zangemeister and M. Wagner attach an addenda to their recent article in the shape of a reference to Hofbauer's observations, the results of which were published in 1897. The latter author found an increase in the number of leucocytes at the beginning of lactation. Zangemeister and Wagner are unable to confirm this,and only find an increase during the puerperium when infection or septic absorption has taken place.

Typhoid Fever without Intestinal Lesions.—Arthur Blumenthal reports a case which was clinically typhoid and which gave a positive widal in a 1-150 dilution. At the time of the attack the patient was in the fifth month of pregnancy. On the tenth day death took place under the clinical picture of a typhoid pneumonia. Upon autopsy tde intestinal tract was found to be absolutely free of typhoid lesions. By artificial cultivation from the spleen, however, typical typhoid bacilli were obtained. The case is of interest in that it is one of a very few in which intestinal typhoid lesions were wanting, and yet the diagnosis substantiated by the cultivation of typhoid bacilli postmortem. from the body.

A New Instrument for the Treatment of Œdema of the Lower Extremities.—H. Citron has modified the instrument which Miura has devised for use in the abstraction of serum from the lower extremities in cases of excessive œdema of the same. The modification essentially consists in the addition of an aspirator of peculiar design to the mechanism of Miura. In this way it was possible to devise an instrument which would extract a much larger amount of serum than that of the latter author, and consequently give much greater satisfaction. In the use of the instrument a small incision is made in the skin over which the "cupping glass" contrivance is applied. The aspirator is then set in operation and the serum withdrawn from the desired location. From 250 to 1,500 c.c. may be thus withdrawn at one sitting and much relief obtained thereby.

Etiology of Eclampsia.—W. Weichardt has inaugurated a series of experiments with the idea of throwing some light upon the etiology of eclampsia. Recently much attention has been given by various observers to the toxins of the placenta and their importance in the causation of eclampsia. It has been thought by many that these toxins when set free in the general circulation would produce the symptom-complex and pathological alterations of this disease unless their power was counteracted by a sufficient amount of specific antitoxin present in the system. In order to more definitely decide this question the author has brought the principles of cytolysis into play in the following manner: Rabbits were inoculated with portions of human placenta, and in this manner there was obtained a serum which was cytolytic for human placenta cells—that is to say, when added to such cells it would break them down and set free the toxin, if any was contained therein. Certain amounts of this serum were then added to human placenta and cytolysis produced. The placenta thus cytolyzed was then inoculated into a series of rabbits and the results noted. Of nine rabbits thus inoculated three died under the symptoms-complex and pathological alterations of eclampsia. Six of the animals were in no way affected by the inoculations. It should not be regarded, however, that the negative results outweigh in importance the positive results, for it is perfectly conceivable that these animals may have possessed a sufficient amount of antitoxin to neutralize the toxin set free by the cytolysis. Although these experiments are not as yet completed, it seems certain that they will strengthen the view which holds that eclampsia is produced by the action of toxins of placenta origin. If this is the case it should be possible, by suitable animal inoculation, to obtain an anti-serum which would be of great utility in the treatment of this disease.

Berliner klinische Wochenschrift, September 1, 1902.

Congestion of the Facial Veins in Progressive Paralysis.—E. v. Niessl emphasizes the importance of congestion of the facial veins, as a diagnositic sign is progressive paralysis. The regions usually affected are the temples and the eyelids. Generally there is more or less œdema of the latter and a peculiar cyanotic appearance of the entire face. These appearances differ from those met with in most other diseases of the nervous system in that they are permanent, and that periods of arterial hyperæmia are never present. The pathological changes have been studied by many observers; they consist essentially of hyaline formation in and hardenting of the vessel-wall. The ganglion cell subsequently becomes affected and dies from malnutrition.

Quantitative Relations of Amboceptor, Complement, and Anti-Complement.—J. Morgenroth and H. Sachs have taken up this question, and by several series of experiments have evolved many interesting facts. For the production of hæmolysis it may be said that, as a general rule, the greater the quantity of amboceptor, the less is the quantity of complement required. This, of course, only holds true within certain limits. It is further interesting to note that this quantitative relation varies with bloods and sera of different origin and with bloods and sera of the same origin at different times. Thus, if we take amboceptors from sheep's blood and complements from guinea-pigs' serum, we find that the relative proportion of complement necessary may be $\frac{1}{32}$, $\frac{1}{4}$, $\frac{1}{10}$ and $\frac{1}{20}$ in four different series of experiments. The reasons for these variations is not clear, but it apparently may be due to any one of the three following causes: (1) The variety and number of receptors present in the red blood-cells; (2) The degree of avidity which exists between the complements and amboceptors; (3) The multiplicity of the amboceptors present. When we come to consider the quantity of anti-complement necessary to prevent hæmolysis we find that this varies with the amount of amboceptor present, the larger the amount of amboceptor the larger the amount of anti-complement required. The end relations, however, vary with the origin of the amboceptors, compliments, and anti-complements. All of these facts show how far from solution and how intricate are the problems of hæmolysis, bacteriolysis, and cytolysis, and how multiple are the factors involved.

Münchener medicinische Wochenschrift, September 2, 1902.

Bone Metasases in Thyroid Tumors.—Richard Wagner reports a case which shows the proclivity of thyroid tumors to bone metastasis. The patient was a female, forty-eight years of age, and had possessed an enlarged thyroid for many years. During childhood there had taken place, from time to time, numerous so-called scrofulous swellings of the superficial cervical glands. About six weeks previous to examination there was a sudden attack of pain in the left hip. This pain so increased in severity that the left leg became useless. Upon examination it was found to be strongly adducted and rotated inward. The glands of the left inguinal region are infiltrated, but painless. The cachectic appearances rapidly increased, and death took place in about two months, under the picture of a profound general intoxication. Upon autopsy it was found that a tumor was present in the neck of the left femur. Microscopical examination showed this to be a spindle-celled sarcoma, which contained many giant cells. The examination of the thyroid showed a similar condition.

Gelatin Treatment of Melæna Neonatorum.—E. Fuhrmann has treated three cases of this disease by the means of subcutaneous injections of gelatin. One case died and two recovered. All three cases were without doubt melæna vera. The case that died was, at the outset, of moderate severity. The gelatin was promptly used, but had apparently no effect upon the hemorrhages. Of the two cases which recovered one was of moderate severity. The other was mild and would have undoubtedly spontaneously recovered without the use of the gelatin. In estimating the value of gelatin in the treatment of this disease it must be remembered that many cases recover spontaneously under any or even no treatment; nevertheless, the value of this treatment is not to be underestimated. Many reports have been made within the past few months concerning its great utility, and the second case here reported without doubt proves its efficacy. In using gelatin in the treatment of hemorrhage the 2 per cent. solution should always be made by the means of physiological salt solution, as local complications are seldom observed when such is used.

Hæmolytic Action of Normal Human Serum.—Martin Hahn and R. Trommsdorff have shown, by a series of experiments, that the complements of normal human serum possess a certain avidity for the amboceptors (immune bodies) of certain heterogenous sera. This question is of importance in serotherapy, since the presence of an excess of heterogenous amboceptors might nullify very largely the action of a specific anti-serum, because the complements present in the blood of the individual might become united to such heterogenous amboceptors, and the specific amboceptors of the anti-serum thus remain without action. Normal human serum is hæmolytic for rabbit or guinea-pig blood. If now to such rabbit or guinea-pig blood first normal sheep serum and then normal human serum is added, the hæmolysis is either entirely prevented or greatly delayed. In the same manner, if we take a specific human serum which is active against horse blood, we find that when normal sheep serum is added to the latter blood, the power of the specific human serum over the same is nullified or greatly weakened. This holds true so long as the quantities of the blood and sera used are maintained at certain definite relations. If the amount of specific human serum used falls below a certain limit, the addition of a moderate amount of normal sheep serum accelerates the hæmolysis. By another series of experiments, the authors show that the hæmolytic power of a given specific human serum against swine blood is greatly lessened or entirely nullified by the addition to such blood of normal human serum of heterogenous origin, while the hæmolytic power is increased by the addition of the normal serum of the same man.

French and Italian Journals.

Subcutaneous Injections of the Yolk of Egg.—G. d'Errico, from his experiments, concludes that the injection of large doses of yolk of egg produces grave renal lesions. Small doses are well tolerated, producing merely slight and temporary alterations, and prolonging the period of resistance to inanition and increasing weight, the resistance to inanition is not to be attributed to real alimentation, but to a retardation of organic waste.—*Giornale Internazionale delle Scienze Mediche*, August 31, 1902.

The Formation of Toxins in Cultures of the Tetanus Bacillus.—A. Bonome describes, at length, his methods of research. He concludes that in the filtrate of anærobic cultures of tetanus prepared in media to which active colitoxin (not heated) has been added, in the proportion of one-fifth to one-fourth of the volume of the medium, the amount of tetanotoxin found is much less than in anærobic cultures of the tetanus bacillus without the coli filtrate. In order to produce the symptoms of slight tetanus in guinea-pigs and rats, about two hundred times as much was required as of the ordinary cultures of tetanus.—*La Riforma Medica*, August 30, 1902.

Double Craniectomy for Brain Lesions.—Annibale Ghedini reports the case of a youth of fifteen years who fell on a three-pronged steel pitchfork and received a perforating wound of the cranium from one side to the other. There was fracture of both parietal bones, laceration of both cerebral hemispheres, depression of a fragment of the left parietal bone, left hemiplegia, right crural monoplegia, epileptiform convulsive movements, and clonic contractions of the right arm, followed by monospasm and then by paralysis. A double craniectomy was performed and the loose fragments of bone removed. The patient bore the operation well, and a few hours later recovered complete consciousness without delirium. By evening the left hemiplegia had almost entirely disappeared and the right arm could move a little. A complete cure followed in two or three months by the aid of massage and electricity.—*La Riforma Medica*, August 29, 1902.

Alimentary Regime of the Arthritic.—Pascault believes that the chief cause of arthritic manifestations is overfeeding. This puts the individual into the position of being obliged to burn up more fuel than he is able to do. The body uses as combustibles the hydrocarbons (starch and sugar) and the fats. But it is active only in the presence of the mineral salts (the phosphates, the chlorides, magnesia, potassium, iron, etc.). The value of food depends upon its nitrogenous principles, on the hydrocarbons, fats, or salts which each kind contains. The heat-giving principles and the minerals are almost exclusively concerned with foods found in the vegetarian régime. The nitrogenous principles are in quantity always more than sufficient, even in a strictly vegetarian diet. Among the heat producers are sugar, fruits, true foods of force, immediately utilizable, and not sufficiently employed; starch, bread, and the fats. The mineral salts ought to vary with the temperament of the individual. On account of their presence in green vegetables and in fruits, these foods are absolutely medicinal for the arthritic. Alcohol is not a food. It is an excitant and a poison to the arthritic, and with the vegetable diet one loses the necessity of alcohol. The food ought to be thoroughly masticated. Methodical mastication and the vegetable diet form the true remedy for the condition of overfeeding and dyspepsia of the arthritic.—*Gazette des Hôpitaux Civils et Militaires*, September 6, 1902.

General Remarks on Operations (Gynecological and General Surgical) at the Maison de Santé des Dames Blanches, 1900-1901.—Henry Barnsby gives a résumé of his operations during the two years (1900–1901). He performed 125 gynecological operations: forty-two by the abdominal method, and eighty-three by the vaginal route, with a total of four post-operative deaths. The first patient who died was operated on for a large papillary cyst of the left ovary, with adhesions. The separation of the intestinal adhesions was very laborious. The left ureter was cut by mistake, together with the pedicle, and the patient died on the fifth day. The second case was that of a woman, fifty-five years old, suffering from an enormous calcified fibroma, included in the broad ligament. The tumor was enucleated, and the broad ligament was sutured with catgut, and the abdominal wound closed without drainage. The patient died the next day with symptoms of internal hemorrhage. The writer regretted not having performed a total abdominal hysterectomy. The third patient was operated on for a large sarcoma of the uterus. Death occurred on the third day from sepsis and circulatory disturbances. The fourth patient was in extremis, when she was operated on for a pelvic abscess, and part of the contents of the abscess had penetrated into the abdominal cavity, and had set up peritonitis, which carried off the patient.—*Archives Provinciales de Chirurgie*, August 1, 1902.

A Case of Tuberculosis of the Liver, of the Spleen, and of the Tracheobronchial Glands; Tubercles Simulating Gummata.—Tolot reports this case of a patient, aged sixty-six years. There was nothing of interest in the family history. The patient had, for a long time, had a tendency to indigestion. Menstruation had always been normal. She was married at fifty, and had never had any children. She showed no evidence of ever having syphilis. She had been in the habit of drinking wine. For the last five years her strength had been gradually declining. For the last two months she had had no appetite, and her weakness was marked. Examination of the lungs revealed only emphysema, but no signs of tuberculosis. The heart was normal; the radials clearly atheromatous. The pulse was compressible. Examination of the liver was negative. There was no splenic dulness. The tongue was lightly coated. The abdomen was slightly tender on pressure. The urine was clear, with no albumin. There was no œdema. In fact, the examination was completely negative. The patient remained in about the same condition for three months, not leaving her bed, and various examinations were negative. The weakness increased till death took place. Autopsy revealed many interesting features. The liver weighed 1,150 grams. It was yellow in color and looked fatty, and the surface looked a little like the cirrhotic liver. There were several nodules as large as a nut appearing on transverse section of the organ. They were gelatinous in appearance. The spleen weighed 480 grams, and presented certain nodules, in appearance like those of the liver. Microscopical examination showed these nodules to be tuberculous. The tracheobronchial ganglia were also similarly affected. The absence of pulmonary and digestive lesions, in this case, is remarkable.—*Lyon Médical*, September 7, 1902.

Ablation of the Stomach.—Jules Bœckel reports a case of cancer of the stomach on which he operated, removing the tumor. It was remarkable on account of its volume, weighing 275 grams; it comprised the entire stomach, with the exception of the left cul-de-sac and the first part of the duodenum. The length was from 17 cm. at the level of the greater curvature to 8 at the level of the lesser; it was 9 cm. in width at the middle point. The neoplasm occupied three-quarters of the two surfaces of the stomach, the pylorus and the first part of the duodenum; the form of the stomach was preserved, and the walls were infiltrated with the growth. The thickness of each wall varied from 3 to 4 cm. The growth terminated in a raised border on the first portion of the duodenum, and on the two surfaces of the stomach. At the cardiac end the border of the tumor was not so prominent. The omentum was scattered with large nodules, and a thick band of it had to be resected. The tumor, which presented on its posterior surface a cyst as large as a nut, was adherent on all sides. When the tumor was entirely separated, it was found impossible to perform a posterior gastroenterostomy, for there was now no posterior surface of the stomach, and gastrectomy was accomplished. The stomach was resected, and what was left of the cardiac end was joined to the first part of the jejunum. The operation lasted three hours and a half. The patient bore the ordeal well, but as this report was made on the third day after, it is impossible to foresee the outcome at this time. The case is interesting, clinically, on account of several features: The man was thirty-six years old; he had suffered for five years; he had never suffered from vomiting, hæmatemesis, or melæna; the tumor, although so large and so easily recognizable on palpation, had escaped, until the past three weeks, clinical experimental researches.—*Gazette Médicale de Strasbourg*, September 1, 1902.

Annals of Surgery, September, 1902.

Note on Synchronous Ligation of Both Internal Jugular Veins.—This operative experience fell to the lot of J. F. Baldwin, in the course of the removal of a tumor of the neck, made up of a collection of tuberculous glands. The vein was accidentally opened on the right side and immediately ligated. The same incident befell the operator when the left side was attacked and some air entered, but not to a dangerous degree. Recovery was without incident. There were no profound central disturbances. The vessels were of normal size, and the operator believes that the long-continued pressure of the surrounding tissues had so far interfered with the return of blood through the jugulars that a fair collateral circulation had already become established.

Operative Treatment of Exophthalmic Goiter.—E. Rixford gives a recapitulation of the various stages of the history of this operation, and discusses its indications and contraindications. He reports two personal cases, in both of which the growth was removed. In both cases the symptoms indicative of Graves' disease were secondary to pre-existing goiter; both cases were chronic and were characterized by increased rapidity of heart action, fine tremor, increased rapidity of respiration, excessive nervous sensibility, diarrhœa, periodical increase of these symptoms, with remissions, constant slight rise of temperature, dyspnœa, general muscular weakness, flushings, and sudden periods of excessive perspiration. In the first case, extraordinary attacks of severe pain in the region of the liver; in the other, a curious, general, non-pitting œdema. In neither case were there characteristic changes in the histological appearance of the tumors. In both cases operation was followed by temporary increase of the nervous symptoms, this followed by gradual remission, the one case having recurrence concomitant with development of a cyst in the remaining portion of the gland, relieved by second operation. No further recurrence of nervous symptoms in either case, the one being observed for two years, the other for seven months. From the standpoint of technique in the operations, neither case is of any particular interest, save that the operations were done without anæsthetic beyond the local use of a small amount of cocaine in the skin, and that the suffering caused by the manipulation of the deeper parts was bearable, and due more to interference with the respiration and the sensation of choking caused by traction on the tumor than to severe pain.

Subparietal Rupture of the Kidney.—From a study of collected cases supplemented by personal experience, T. A. Davis offers the following conclusions: (1) That the reduction in the mortality since Keen's report has been largely due to improved technique. Fewer deaths have been reported from sepsis. Several deaths have been reported from hemorrhage, which could undoubtedly have been avoided if more prompt and efficient means had been resorted to. He predicts that the mortality will be reduced to 15 per cent. (2) The expectant plan of treatment is permissible in cases where slight hæmaturia is the only symptom. Tumefaction—much blood in the urine, severe pain, and history of great violence, each is a positive indication for prompt operative intervention. (3) Early operations should be done in all cases where the history of the case and the symptoms point to serious injury of the kidney. (*a*) Nephrotomy, with gauze tamponage where the patient has not lost enough blood, so that little subsequent hemorrhage would not endanger life. (*b*) Nephrectomy where the kidney is irreparably injured, and in less extensive injuries where either sepsis or hemorrhage is likely to prove fatal. (4) In delayed cases it may be difficult or impossible to know just what is best to do. Every phase of the case must be considered, and then, if in doubt, operate. (5) Shock is the violent disturbance of the nervous system immediately consequent upon injury. While there is some ground for hesitation in those cases of true shock, most of the cases described as shock are depression of the vital force from hemorrhage or sepsis, and nothing short of prompt surgical intervention will prevent collapse. (6) Let operation be determined by the history of the case rather than wait for symptoms which may only suggest what should have been done earlier, but at last proclaim without hope for relief.

Removal of the Superior Cervical Ganglion for the Relief of Glaucoma, with Report of a Case. C. W. Cutler discusses the mode of formation of glaucoma, and briefly reviews the results of iridectomy which has so long been the classical operative procedure. More recently it has been proposed to remove the superior cervical ganglion of the sympathetic-sympathectomy, as the operation is styled. Too few cases are thus far on record to enable a comparison to be made with the older procedure. Two years' impartial observation can alone permit definite conclusions to be drawn. The details of one case are given by the author who analyzes recent literature on the subject. He says that one symptom may be mentioned, which if proven to exist in certain cases of glaucoma, will help to distinguish such cases as are dependent on the influence of the sympathetic ganglion. He refers to retraction of the lids or Von Graefe's sign, which in three cases of chronic glaucoma, seen recently, has been more marked than is usual in optic atrophy or impaired vision from other causes. It does not seem amiss to associate this symptom with the large, sluggish pupil and increased tension of glaucoma, since all are influenced by sympathectomy. In one case of unilateral glaucoma this sign is present only on the affected side. It is not as pronounced as it often is in Basedow's disease, but resembles the effects of cocaine. Von Graefe's sign is sometimes seen where there is no disease, and in normal eyes and in these cases it may be merely a result of the effort to see better, but the case in which it is present only on the side of the glaucoma is certainly suggestive. The operation in Cutler's case was done by C. L. Gibson, who thus describes the plan followed: A straight incision running downward from the mastoid along the anterior border of the sternomastoid. The sheath of the vessels having been exposed, the vessels and pneumogastric nerve were reflected inward, and after some further dissection the sympathetic ganglion was found posterior to the aforementioned structures. A painstaking dissection of the connections of the ganglion was made before division of the nerve above and below. The wound was sutured without drainage and healed *per primam*. Convalescence was uneventful. The patient was allowed up on the ninth day, and was discharged ten days later.

On the Avoidance of Shock in Major Amputations by Cocainization of Large Nerve-Trunks Preliminary to Their Division.—Harvey Cushing notes that injuries of the most diverse nature to peripheral nerves may, especially in some physical states, produce, reflexly, a fall in blood pressure, and that this loss of vascular tone, when it endures, is the most characteristic feature of shock, the symptom-complex of which is largely due to this one factor. He finds that local anæsthetization of a nerve-trunk will block the transmission of the centripetal impulses, which otherwise might bring about this reflex loss of vascular tone. Experimental observations have shown that the weakened or paralyzed condition of the vasomotor center in the medulla, brought about reflexly by the mechanical injury to peripheral sensory neurones, plays the chief *rôle* in inaugurating a state of shock. The loss of control over the general arterial tone which results from this weakening of the center results in a determination of blood in certain vascular fields. Of these the largest and most important is the great splanchnic territory the flooding of which side-tracks, as it were, such an amount of blood that there results an anæmia of the brain and lungs, a weakened cardiac action, or the "empty pump" principle of Goltz, and a consequent great fall in blood-pressure. Comparatively recent observations have been largely instrumental in establishing the view that in each bundle of mixed peripheral nerves there exist definite centripetal (pressor) fibers, stimulation of which calls forth by reflexations a vasoconstrictor response, and others equally definite, which, on the other hand, produce, when stimulated, a depressor effect from reflex vasodilatation, with consequent fall in blood-pressure. In the neck of the rabbit, as is well known from the classical experiments made in Ludwig's laboratory, afferent fibers subserving in certain measures these different functions, run apart, and may be individually stimulated. One of these nerves has become known in consequence as "the depressor nerve," and must not be confused with the depressor fibers supposed to be present in other mixed nerves. Under ordinary circumstances, however, in the neck as well as in the nerves of the extremities, both pressor and depressor fibers run together in the same trunk, and due to the fact, that the former, under normal conditions, respond more readily and effectually to most forms of stimulation a rise in blood-pressure is usually produced. Of these two sets of fibers, those having a pressor action seem to be the first to suffer from injury or over-stimulation, and when, in consequence, they have become exhausted, the same irritation to the mixed nerve which previously would have called forth a vasoconstrictor action, then elicits a fall in blood-pressure from stimulation of the still active depressor fibers.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CANADIAN MEDICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held in Montreal, September 16, 17, and 18, 1902.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

Tuesday, September 16.—First Day.

At the morning general session of the first day a resolution of regret at the recent death of Professor Virchow, which was at the same time one of appreciation for the great work of this eminent pathologist, was proposed by Professor Adami, seconded by Dr. Gardner, Montreal, and carried unanimously.

Address in Surgery—The Contribution of Pathology to Surgery.—Dr. JOHN STEWART, Halifax, N. S., the author of this address, was absent, and the address was read by Dr. J. W. Stirling of Montreal. In this address Dr. Stewart, in commencing, compared the struggles of the early surgeons for a scientific knowledge of their craft to the daring exploits of the early navigators of the fifteenth and sixteenth centuries—a parallel not altogether fanciful might be drawn between those pioneers of ocean travel and the early masters of our craft. They worked on two lines, the long, weary, and often fallacious track of empiricism, and the ample, but often disconnected, road constructed by those whose chief aim was, in the words of him who led the vanguard, to "study and search out the secrets of Nature." The first advance came with the anatomist, Vesalius, "and day dawned with William Harvey, the Columbus of modern medicine," when he instituted the application of experimental methods to biological questions.

Finally came John Hunter, "the father of scientific surgery," of whom Billroth has said that "from the time of Hunter to the present, English surgery has had something of grandeur and style about it." But a great advance came from the study of plant life, and the researches of Schwann and Schleiden paved the way for the cellular pathology of Virchow, which is the basis of our present system of pathology. "And," said Dr. Stewart, "a shadow falls upon us gathered here, as we realize that the Veteran Master the undisputed leader of pathological thought and progress for over fifty years, has fallen, and we unite in the desire to lay our spray of cypress on the tomb of him whom we all considered the greatest German of our time."

While with all these new acquisitions the pathologist went on his way rejoicing, the surgeon still lingered with anxious mind and heavy heart, for the question of questions to him was still unanswered—the healing of wounds was the enigma of surgery. By the close of the eighteenth century, many scientific workers were satisfied the solution of this problem lay in the existence of pathogenic microbes, but it was reserved for Schonlein to prove, in 1839, that finea was due to the growth of a fungus. Later came Davaine and Chaveau, with their demonstration of the bacillus of anthrax. And finally came Lister, "and," said Dr. Stewart, "the dark hemisphere rolled in one grand movement from its age—long penumbra into noonday. Surgery, modern surgery, was born. In the chronology of our craft, time is divided into Before and After Lister." Lister, like Hunter, united in himself the pathologist and the surgeon, and, like him, worked on the lines of experimental pathology.

President's Address.—On the evening of the first day, in the Arts Museum, Dr. FRANCIS J. SHEPHERD of Montreal delivered the annual presidential address. After welcoming the members, Dr. Shepherd spoke of the Dominion Registration Bill, which has been so ably pushed through, in the face of many obstacles, by Dr. T. G. Roddick, and expressed the hope that no one province would decline to act in accord with the almost universal desire to see the bill finally made law. After a brief résumé of medical progress, the speaker entered a protest against the freedom with which syphilitics are allowed to mingle with the community at large, often causing the innocent to suffer more than the guilty. "It is time," said Dr. Shepherd, "that the profession took this subject up and educated the public to a better knowledge of sanitary laws." Passing on to the subject of modern laboratory teaching, the president said, after referring to the large sums of money that have been spent on the erection and endowment of laboratories for the encouragement of research work, "One danger of this great multiplication of laboratories is that it induces men to pursue original investigation who have not the true scientific spirit, and who are utterly unfit for such work. They frequently collect and publish a mass of useless and undigested material and therefrom draw inaccurate conclusions. All this will not redound to the credit of medical science. "But," continued Dr. Shepherd, "I do not wish it to be inferred that I am opposed to the addition of modern laboratories to our medical schools. They are all necessary, but they must not supplant other work quite as important to a man who wishes to become a practising physician or surgeon. Again, we must remember that the millennium will not be brought about by laboratories, nor will all scientific problems be solved by them. There is one laboratory which is not so much frequented now as when I was a student. I refer to the hospital wards. Students, while perhaps more scientific—I say scientific because nowadays every one who spends much of his time in a laboratory learning the use of all kinds of modern apparatus, including our old friend the microscope, is regarded as having a scientific training—I may say that students, while perhaps more scientific (microscopical and mechanical), have not the intimate personal knowledge of disease which continued observation at the bedside gives them, so that when started in some out-of-the-way place without their scientific machinery, they are like fish out of water. It may soon be that they will not be able to diagnose a fracture without the *x*-rays, tuberculosis without getting bacilli in the sputum, and so on without end. Students are not taught to observe so accurately the evident symptoms of disease, and, as I say, are becoming mere mechanics who need an armamentarium, which only a great hospital or university can possess, to make an accurate diagnosis of an ordinary disease; the higher and more intellectual means of drawing conclusions by inductive reasoning are almost neglected. Mind you, I do not wish to disparage laboratory teaching; it is essential, but we can have too much of a good thing, and laboratories nowadays take up too much of the student's time in the latter years of his curriculum. The ordinary student should have a good working knowledge of laboratory methods, and this should be obtained chiefly during his first two years, but the refinements, if insisted, will be acquired at the expense of some more useful and practical information, for the average student can only hold so much knowledge—it is hopeless to attempt to put a quart measure into a pint pot."

Speaking of specialism, Dr. Shepherd held up the ideal of all-round knowledge. He thought all doctors should acquire a good working knowledge of all specialties, but an excess of time should not be devoted to any one. A year or two of hospital work, followed by some experience in general practice, should be managed by any one who wishes to become a broad-minded specialist.

At the close of his most interesting address Dr. Shepherd paid a high tribute to the late Dr. Wyatt G. Johnston, Dr. Wm. S. Muir of Truro, and Dr. Brunelle of the Hotel Dieu.

Wednesday, September 17.—Second Day.

Diseases of the Gall-bladder and Bile-ducts.—Dr. ALEXANDER McPHEDRAN, Toronto, introduced the subject of the medical diagnosis in this discussion. He mentioned the fact that the gall-ducts were narrower at their entrance to the bowel than in other parts of their lumen, and as they lay nearly horizontally the outflow of bile was easily retarded or obstructed. The ducts were much exposed to infection from the intestinal tract. Of the cardinal symptoms in these cases, Dr. McPhedran considered jaundice the most common, while pain varies, but was generally intense. The attendant fever was generally due to toxic absorption. The main diseases to be considered in differential diagnosis were catarrhal and suppurative cholangitis and acute yellow atrophy. Most catarrhal conditions were infective, but the chills and fever might occur without pus formation. The most common germ present was the common colon bacillus. In the gangrenous cases the symptoms were often ill defined. A most characteristic sign of gallstone was the recurrence of the attack.

Dr. A. D. Blackader, in discussing the treatment of gall-bladder affections, said he would confine himself principally to catarrhal forms of the disease. He considered the condition more commonly due to altered secretion of the bile-ducts, the altered mucus causing inspissation of the bile. Infection of bile, he thought, took place in two ways—through the bile-ducts and through the portal circulation. In the matter of treatment he considered that no drugs stimulated the flow of bile to the same extent as the bile salts. The flow was increased by exercise and deep breathing. The diet should be carefully considered, should be simple, and, as far as possible, should contain a large amount of fat. Such patients should drink plenty of pure water or mineral water. The patient should also have due regard to a proper method of dress, no corsets or constricting clothing should be worn.

Dr. James Bell of Montreal spoke of the surgical diagnosis. He said it was common to find early vague symptoms of gastrointestinal indigestion, which were often found to be present for a long time before an acute attack was precipitated. He spoke of the colon bacillus and the typhoid bacillus as common causes of infective conditions.

J. F. W. Ross of Toronto took up the subject of surgical treatment. In commencing his paper Dr. Ross expressed a certain lack of faith in the so-called medical treatment of gallstones. Speaking of some details of gallstone operations, Dr. Ross advocated drainage through Morrison's pouch. He laid great stress on the free use of gauze packing to prevent leakage into the peritoneal cavity. In gangrene and empyema of the gall-bladder he did not advise removal of the gall-bladder, but preferred opening, flushing, and draining. In many cases of cystic enlargement of the gall-bladder, however, he advised entire removal of the viscus. It was well to remember, after the removal of the gall-bladder, that gallstones might form in the liver and be passed out into the intestines. He considered mucous fistulæ, which occasionally followed operation, as the most troublesome, and said the evil should, as far as possible, be prevented by the use of a small drainage tube. He also drew attention to the importance of being sure that the drainage tubes did not become blocked.

G. E. Armstrong of Montreal led the discussion of the surgical treatment. He recognized and recommended the employment of medicinal treatment first in gallstones, etc. He did not advise removal of the gall-bladder for stone in the cystic duct. He recommended lavage of the stomach before operating on all gall-bladder cases, and, as it was difficult to know what the surgeon might encounter on opening the abdomen, he advised the administration of calcium chloride before and after operation, to prevent possible hemorrhage.

Dr. Dudley Allan of Cleveland, Ohio, next spoke on the importance of early operation on the gall bladder. In view of the fact that an accurate diagnosis was often impossible, he considered an exploratory incision, at least, should generally be made early, when, he claimed, it was often found that many obscure cases were quite amenable to surgical treatment, and, in fact, would fail to recover if we were to temporize. He reported a number of cases in which the diagnosis was uncertain, in which he had made an exploratory incision, and had often been gratified with the results.

The subject was further discussed by Sir William Hingston of Montreal and Dr. Alex H. Ferguson of Chicago.

Foreign Bodies in the Vermiform Appendix.—Dr. James Bell of Montreal expressed the opinion that appendicitis never depended on the presence of foreign bodies in the lumen of the appendix. There was little doubt, however, that when foreign bodies gained entrance accidentally into the appendix, they aggravated an otherwise septic infection. Among the foreign bodies which he had found in the appendix were in two cases pins, in two cases seeds, in one case wood fiber, in one case gallstones, and in another case a fish bone.

Dr. Bell's paper was further discussed by Mr. Irving Cameron of Toronto.

Address in Medicine.—Dr. Wm. Osler of Baltimore delivered this address. He first spoke of the noble ancestry of our profession. The outlook for the profession, he said, was never brighter than to-day. Many of the diseases of our grandfathers were vanishing. The orator then put forward a strong plea for the unity of the profession. A sense of self-satisfaction was all too common in the medical ranks as in other walks in life. Chauvinism was an enemy to progress. He mentioned four forms of Chauvinism, namely, national, provincial, parochial, and individual. Nationalism was apt to become a widespread vice in so far as this concerned the medical profession, but international medical congresses had done much to dispel this spirit. Dr. Osler strongly advised young men to go abroad for post-graduate study, especially those who aspired to teach. If this were not possible, he strongly recommended the study of foreign medical literature. It helped a man, he said, to be a bit of a hero worshipper. Continuing, he said that there was a remarkable homogeneity of the profession on this continent, still there was no little provincialism among its numbers. Witness the various provincial medical councils in Canada and the various state boards in the United States. He considered it an outrage that a graduate of Ontario could not practice in Quebec, or a graduate of Quebec in Manitoba; it was democracy run riot, it was provincialism. The solution of this problem rested with the general practitioner. Dr. Osler here paid a high tribute to Dr. Roddick for his energy in pushing through the Dominion Medical Bill. Passing on to speak of parochial Chauvinism, the writer said all were tainted with it to some extent. A good method of counteracting this was to encourage professional interchanges.

Chauvinism in the unit, however, was of much more interest and importance. The consultants did the writing, and the talking, and took the fees; the backbone, however, of the medical profession was the general practitioner. But he should preserve his mental independence and keep up with the times in literature and appliances. Diagnosis, not drugging, was our chief weapon of offense. Lack of systematic personal training in the methods of the recognition of disease led to the misapplication of remedies, to long courses of treatment, when treatment was useless, and so directly to that lack of confidence in our methods which was apt to place us in the eyes of the public on a level with empirics and quacks. One should not degenerate into a mere dispenser of quack nostrums like the drug clerk who has a specific for everything from the pip to the pox. Dr. Osler said that learning alone was not sufficient, culture was the bichloride to keep one from intellectual deterioration; and, lastly, there should be charity among the profession; all should make the golden rule the code of ethics, and should adopt the motto of St.

Ambrose. "If you cannot speak well of your brother, keep silence."

Thursday, September 18.—Third Day.

Election of Officers.—Dr. T. G. Roddick, M. P., Chairman of the Nominating Committee, presented the report of this Committee. London, Ont., was selected as the next place of meeting. The following officers were elected:

President: Dr. W. H. Moorhouse, London, Ont. *Vice-Presidents:* Prince Edward Island, James Warburton; Nova Scotia, John Stewart, Halifax; New Brunswick, W. C. Crockett, Frederiction; Quebec, Dr. Mercier, Montreal; Ontario, Dr W. P. Caven, Toronto; Manitoba, Dr. McConnell, Morden; Northwest Territories, J. D. Lafferty, Calgary; British Columbia, C. J. Fagan, Victoria. *Local Secretaries:* Prince Edward Island, C. A. MacPhail, Summerside; Nova Scotia, Dr. Morse, Digby; New Brunswick, J. R. McIntosh, St. John; Quebec, R. Tait McKenzie, Montreal; Ontario, Hadley D. Williams, London; Manitoba, J. T. Lamont, Trehern; Northwest Territories, D. Low, Regina; British Columbia, L. H. McKechnie. *General Secretary:* George Elliott, 129 John street, Toronto. *Treasurer:* H B. Small, Ottawa. *Executive Council:* Drs. Moore, Eccles, and Wishart, London, Ont.

Dominion Health Bureau.—Dr. E. P. Lachapelle, Secretary of the Board of Health of the Province of Quebec, moved the following resolution, seconded by Dr. J. R. Jones, Winnipeg, which was carried unanimously:

"*Whereas*, Public health, with all that is comprised in the term sanitary science, has acquired great prominence in all civilized countries, and

"*Whereas*, Enormously practical results have been secured to the community at large by the creation of health departments under governmental supervision and control, and

"*Whereas*, Greater authority and usefulness are given to health regulation suggestions when they emanate from an acknowledged Government Department;

"*Therefore*, Be it resolved that in the opinion of the Canadian Medical Association, now in session, the time is opportune for the Dominion Government to earnestly consider the expediency of creating a separate department of public health, under one of the existing ministers, so that regulations, suggestions and correspondence on such health matters as fall within the jurisdiction of the Federal Government may be issued with the authority of a Department of Public Health. That copies of this resolution be sent by the General Secretary to the Governor-General in Council, and to the Honorable the Minister of Agriculture."

Treasurer's Report.—Dr. H. B. Small presented this report. Three hundred and seventeen members had been in attendance, nearly one hundred larger than at any other previous meeting. All outstanding indebtedness had been paid, and there was in the treasury $325 to the good of the Association. This announcement was received with the greatest satisfaction. Votes of thanks were passed to Mr. and Mrs. James Ross, of Montreal, in whose handsome grounds had been tendered a garden party on the afternoon of the first day; to the Local Committee and Transportation Committee, special reference being made to Drs. C. F. Martin and J. Alex. Hutchison, for their indefatigable efforts for the success of the meeting; to the Treasurer, the President, and the profession generally for their hospitality. Thus was closed the greatest meeting in the thirty-five years of the Association, and it is to be hoped that the profession throughout Canada will still further take an active interest in the national organization.

MEDICAL SECTION.

Tuesday, September 16.—First Day.

Splenic Anæmia.—Dr. H. A. Lafleur, Montreal, presented this patient—a man in middle life. There was a tumor—a movable mass about midway between the lower ribs on the left side and the crest of the ilium, with pulsation (not expansile) over the tumor. The first blood count, made in March, showed 75 per cent. hæmoglobin; the red corpuscles, 5,000,000; the white, 6,400. A blood count was made again on the 15th of September, 1902; and showed 4,000,000 and 5,800, respectively. The tumor changed according to the degree and distension of the stomach. There was absence of mobility.

Some Further Results in the Treatment of Tuberculosis.—Dr. J. H. Elliott of the Gravenhurst Sanatorium contributed this paper. At a meeting of this association in Toronto, in 1899, a report was made upon 155 cases of pulmonary tuberculosis under sanatorium treatment. This paper was a further contribution, covering some 400 additional cases treated during the past three years. The nomenclature used in the classification of discharged patients was that adopted by Trudeau: "apparently cured;" "disease arrested;" "much improved;" "stationary," and "failed." Five years' experience had shown that almost all of the patients discharged "apparently cured" remained perfectly well; of those with "disease arrested" many had progressed to good health at home by following the rules of life learned at the sanatorium, renewed activity of the disease, when occurring, having been, as a rule, due to unfavorable sorroundings, or the necessity of again taking up unsuitable work. Not the least important part of the work of a sanatorium was its educative influence. Each patient who returned home was a teacher of the value and importance of a hygienic life to those who wished to retain their health, as well as those who were not strong.

Experience was demonstrating the immense amount of influence for good which resulted from a properly equipped and conducted sanatorium. It was unfortunate that there were not more of them. It was hoped that the attention of our philanthropists would be drawn to the crying need of such institutions, and that ere long we should have a number of them in the various provinces of Canada.

Dr. Osler congratulated Dr. Elliott on the promising results which he had obtained. Two important points should be kept well in mind: First, early diagnosis; and second, getting patient as soon as possible under proper professional control.

Dr. T. D. Walker, St. John, N. B., referred to the control the physician in the sanatorium had over the patient.

Dr. John Ferguson, Toronto, spoke of the positive advances that have been made along the line of the curability of pulmonary tuberculosis.

Dr. McPhedran, Toronto, emphasized training patients how to care for themselves at home. He believed, too, that it was true that the neighborhoods of sanatoria were areas where tuberculosis was always diminishing.

Pleurisy as Associated with Tuberculosis.—Dr. John Hunter of Toronto read this paper. He first referred to the manner in which bacilli reached the visceral and parietal pleural through the subpleural, bronchial, or tracheal lymphatic glands, and from the cervical, mediastinal, and peritoneal lymphatics; also from the tonsils. In arriving at a diagnosis of pleurisy, a vigilant search should be made for a possible tuberculosis origin. One should not always consider the outlook gloomy, as with properly-carried-out treatment the progress is much more favorable than in pulmonary tuberculosis. In at least two-thirds of tuberculous pleurisy it is a curable affection. The rapidity of the filling of the pleural cavity is especially characteristic of tuberculous cases. Dwelling upon treatment, during convalescence, deep breathing should be practised very assiduously, and inflation with rubber bags was a valuable exercise. Then change to a suitable climate should be insisted on if the progress toward recovery was retarded.

Clinical Notes on Blood Pressure in Diseased Conditions.—Dr. A. E. Orr, Montreal, read this paper. A. Gaertner's tonometer was shown and the manner of its use demonstrated. Four hundred patients at the Royal Victoria

Hospital, Montreal, were experimented on. The normal pressure was found to be 110 to 120. Seventy cases of typhoid fever were recorded in different stages, showing an average blood pressure of 104.5 m.m It was highest, but still sub-normal, in the first week. There was only one death, which took place in a man of thirty-five years, when pressure was 105 on the tenth day, 110 on the twenty-first day; then occurred three hemorrhages, and on the twenty-fourth day a fatal hemorrhage. A large proportion of these had cold baths or cold sponging.

Nineteen cases of chronic nephritis were recorded Of this group the highest was 260; average 208 5. Of acute nephritis there were seven cases; only three of these showed high pressure. Of arterio-sclerosis twenty-seven cases were recorded: highest 110, sixteen being 150 and over; four from 130 to 145; three from 110 to 125; four subnormal. The highest was in a man of seventy-two; glycosuria, no albumin.

Valvular diseases of heart, forty-eight cases, including eleven cases of mitral regurgitation. In mitral stenosis eight cases were recorded, six being normal. Mitral stenosis with mitral regurgitation, fourteen cases. Eleven had practically normal tension. Aortic insufficiency, three cases. Myocarditis, four cases; one man, aged sixty, having pressure of 80. Hypertrophy and dilatation of heart of unknown causation, two cases, 120 and 110 respectively.

There were eighteen cases with actue lobar pneumonia, with an average for the series of 92.7; only one death. Pleurisy, sixteen cases. Neurashtenia, eighteen cases, thirteen having normal pressure; three from 135 to 140; one of 160. In malignant disease, cancer of viscera, there were no high readings. Anæmia, six cases, all being normal. Addison's disease, two cases, both in early stage; both normal. Puerpera hæmorrhagica, one case, normal. Puerperal septicæmia, one prolonged case, ending in recovery, had extremely low blood count; 930,000; above normal. One gall bladder case with suppuration—a blood pressure of only 50 ten days before death.

One lead poisoning, three of jaundice, one of tuberculous meningitis; two of diabetes; two of exophthalmic goitre; eight of acute articular rheumatism, heart not affected; chronic articular rheumatism, four cases, all normal; gonorrhæal rheumatism, eight cases, six normal; rheumatoid arthritis, sixteen cases, six normal; gout, four cases.

There was one case of hemiplegia and fourteen of tabes dorsalis, eleven normal pressure; cerebral tumor, eight cases; general paralysis of the insane, one case; Friedreich's ataxia, one with albuminuria, 140; one acute ascending paralysis, 140; two cases tic douloureux, one 130 during the attack. There was one case of epidemic influenza and thirty-six miscellaneous cases.

Wednesday, September 17.—Second Day.

Kernig's Sign, the Frequency of Occurrence, Causation, and Clinical Significance.—Dr. R. D. Rudolf of Toronto read this paper, which contained the results of an investigation carried out in the different hospitals of Toronto. A large number of patients of all ages were examined, suffering from divers troubles, and the angles at the hip and knee accurately measured in over 200 of them. In 162, Kernig's sign was present in ninety-seven; that is, in over 60 per cent. It was always absent in perfectly healthy children. Dr. Rudolf considered that a more convenient plan was to extend the knee and then flex the hip as far as possible. Sometimes there was more than the usual degree of stretching of the ham string possible, and this extra flexion could, by the writer's method, be exactly measured when Kernig's sign did not show it. Of the ninety-seven cases, in which Kernig's sign was present in fifty-nine, an angle of less than 165 degrees at the knee could be obtained, and of these, in ten cases, the angle was 135 degrees or less, showing a very marked degree of the sign. These fifty-nine cases were of all kinds, and only one of them was of meningitis. Dr. Rudolf then went on to state that none of the theories of explanation of Kernig's sign were [illegible] it [illegible] meningitis.

Multiple Sarcoma, Report of a Case. The [illegible] reported by Drs F N G Starr and J J MacK[illegible] Toronto Dr MacKenzie read the notes on the ca[illegible] No autopsy could be made The patient was a woman [illegible] years of age, a seamstress The personal or family history had no bearing on the case. For a number of year before 1901 the patient had a goitre, which, under treatment, almost disappeared in the winter of 1901 In April, 1901, a lump about the size of a pea was noticed slightly to the left of the middle line of the abdomen, near the symphysis pubis, hard but painless and subcutaneous In May two or three appeared in the middle line, an inch above the umbilicus; then two or three were discovered in the back. In June two others appeared to the right of the middle line of the abdomen In July several additional lumps were discovered in the right breast, in size from a pea to a bean. Loss of weight occurred In August the liver was noticed to be enlarging. Commenced taking arsenic in September. In October a large tumor appeared in the left breast, and a small one was also noticed in the left thigh. Patient began to suffer from rheumatic pains. In November and December the tumors appeared in enormous numbers over the chest and back, abdomen, thighs and arms above elbows, neck and over back, sides and top of head. In January, 1902, chains of tumors, bean-sized, were noticed in the cervical region, submaxillary and suboccipital regions. By March 8 she had thousands of tumors, most quite hard. Excisions were made and microscopic examination revealed a type of spindle-celled sarcoma, in which the prevailing cell was very long. As regards treatment, the patient took arsenic with no influence on the condition. Thyroid extract produced slight diminution in the size of the tumors. Patient died. Without autopsy one cannot say where the primary seat of the disease was, although from the great involvement of the liver, that might be the source of the disease.

SURGICAL SECTION.

Tuesday, September 16—First Day.

Amputation of the Upper Extremity for Sarcoma of the Shoulder Joint.—Dr. J. Alex. Hutchison of Montreal presented the patient—a young woman— who gave a history of previous injury to the shoulder, followed by the development of a growth in the head of the humerus, accompanied by intense pain. An *x*-ray of the parts revealed the presence of a large growth which invaded the joint, and involved the scapula. The patient was in an extremely unsatisfactory condition for operation, and presented evidences of marked cardiac disease. The incision extended from the middle of the clavicle in front down over the pectoral regions to the lower part of the axilla, and behind, passed over the scapula down to meet the anterior incision. After severing the middle of the clavicle, the great vessels were ligated, the brachial nerves divided high up, the muscles divided, and the scapula freed from its attachments. There was little hemorrhage and the wound healed readily. Microscopic examination of the growth showed it to be a mixed spindle and round, called myeloid sarcoma.

A Fatal Case of Secondary Hemorrhage Four Days Following the Removal of Adenoids.—Dr. Perry G. Goldsmith of Belleville, Ont., read this paper, which dealt with the case of a child operated on by Dr. Goldsmith for obstructive deafness due to enlarged faucial tonsils. The operation was not unusual, and the condition of the patient, on the second and third day after the operation, was apparently satisfactory; on the fourth day, however, repeated and alarming attacks of hemorrhage set in, resulting fatally in a few hours. There was no history of hemophilia. The patient was under the care of the family physician at the time of death, and as no post mortem could be obtained, the cause of the hemorrhage remained unknown.

Occlusion of the Posterior Naris.—Dr. H. D. Hamilton of Montreal reported the case of a young man, aged seventeen, who complained of constant discharge from the right naris, with complete obstruction of the same side. The duration of the condition had been about twelve months. On examination, the patient presented a complete bony partition, occluding the right choana. Family and personal history was negative. Treatment—the bony wall was perforated, and the opening further enlarged by graduated bougies.

Subcutaneous Injections of Paraffin for Correcting Deformities of the Nose.—Dr. G. Grimmer of Montreal spoke briefly of various deformities which had been corrected in this manner. The paraffin was first sterilized by subjecting it to high temperature. It was then injected by means of a sterilized syringe. In the case of the nose, the inner canthi of the eyes should be protected from the spreading of the paraffin, by firm pressure applied to the sides of the nose by an assistant's fingers. After injection, the parts should be molded by the operator as required. After treatment—Collodion was to be applied to the needle puncture, and cold compresses, to control œdema of the nose and eyelids. Some possible dangers from the treatment were paraffin embolism and necrosis of the skin over the parts. Dr. Grimmer exhibited two patients successfully treated in this manner; also two rabbits which had been subjected to similar injections.

The Telephonic Properties of the Inflamed Abdomen; a Sign not Hitherto Described, due to Paralysis of the Bowel in Peritonitis.—Dr. George A. Peters of Toronto, read this paper. In auscultating the abdomen with a view to ascertaining whether there was paralysis of the bowel in cases of appendicitis, typhoid perforations, traumatism, and other conditions which stand in a causative relation to peritonitis, Dr. Peters had observed that where the gurging sounds due to the passage of gas and liquid in the bowel were absent by reason of paralysis, the heart sounds were invariably very plainly present over the whole abdomen. In intense cases, particularly in children, both inspiratory and expiratory breath sounds might be heard. Dr. Peter's explanation of the phenomena was that unlike the healthy bowel—in which the gas was retained in certain well defined and circumscribed compartments, each constituting a complete retainer in itself, with vital walls possessing a muscular tonicity under nervous control, the paralyzed bowel, by reason of its flaccid and atonic condition, permitted an entire change in the disposition of the contained gas: the entire distended abdomen becomes practically and accoustically considered, a continuous column of air or gas, of the precise principle of the stetheoscope. The effect of this was further heightened by the rigid abdominal wall, which acted as a sounding board. The prognostic significance would seem to indicate an unfavorable termination in those cases in which the sign was very well marked in cases of septic origin.

A Case of Filariasis in Man Cured by Operation.—Dr. A. Primrose of Toronto, reported the case of a man from the West Indies suffering from lymph scrotum, who presented himself for treatment and gave a history of attacks of fever which suggested the presence of filaria. On examination of the blood the embryos were found to be present in large numbers. The embryo filariæ were found in large numbers at night, but disappeared from the blood during the day. An operation was performed and a large portion of the scrotum removed. The excised tissue was carefully examined by teasing it in salt solution, and a parent worm was discovered and removed alive. This proved to be a female, and it was subsequently fixed and mounted in a suitable manner for microscopic examination. Subsequent to the operation the filaria embryos entirely disappeared from the blood, and the influence was that the parent producing the embryos had been removed by operation. The parent worm was afterwards carefully studied by Dr. J. H. Elliott, M.D., Toronto, (late of the Malaria Expedition to Nigeria from Liverpool School of Tropical Medicine) and a report of his investigations with drawings of the worm formed a part of the paper as communicated by Dr. Elliott.

Wednesday, September 17.—Second day.

Three Cases of Congenital Dislocation of the Hip.—Dr. A. E. Garrow of Montreal read this paper. The etiology of this condition was not well established, but heredity seemed to play a part. Dr. Garrow spoke of two methods of reduction—(*a*) bloodless method, (*b*) through an incision. The chief obstacle to reduction was generally fibrous stricture of the lower part of the capsule. Dr. Garrow's experience had been mainly by the open method.

The Operative Treatment of Goiter with a Report of Cases.—Dr. Ingersol Olmstead of Hamilton, Ont., presented this communication. As the medical treatment of goiter was very unsatisfactory, an operation was recommended in the following conditions: (1) As soon as goiter became dangerous—that is, when attacks of dyspnœa or inflammatory changes occurred—or there was the slightest suspicion of malignant degeneration. (2) All enlarged thyroids having a tendency to grow toward the aperture of the thorax, even if they were movable. (3) Goiters that have reached considerable development from the formation of single large colloid nodes. (4) When with a moderate goiter, symptoms like those of Graves' disease appeared, accompanied with an increased development of the goiter. The operation advised was the one usually performed by Kocher, and was done under cocaine anæsthesia. It consisted of a transverse, symmetrically-bowed incision, with its convexity downward, from the outer surface of one sternomastoid muscle to the other, higher or lower, according to the position of the goiter. The skin, underlying platysma, and fascia of the sternohyoid and sternotyhroid muscles were reflected upward. The fascia joining the muscles in the median line of the neck was then divided as well as the outer fibrous capsule of the gland. The half of the gland which was most involved was then shelled out of its capsule, the superior and inferior thyroid arteries tied, the isthmus cut with goiter clamp, and ligated.

The remaining attachments were then ligated and portion removed. The wound was closed with a subcuticular wire suture without drainage. Twelve cases operated on during the past year were reported. The average stay in the hospital was seven days. The resulting scar was very slight, and little or no pain was complained of during the operation.

The Pathological Prostate and Its Removal Through the Perineum.—Dr. Alex. H. Ferguson of Chicago, Ill., in opening, said he proposed to discuss more particularly hypertrophy of the prostate. Some of the macroscopical changes in the hypertrophied prostate were: (1) Increased weight—even up to eight or nine ounces; (2) Greater size; (3) Any part or the whole of the gland might be involved. The shape varied very much. Microscopically, Dr. Ferguson found all hypertrophied prostates were benign in character. He also found frequent evidences of inflammatory changes. The effects produced might be stated as: (1) The prostatic urethra was contracted and elonged; (2) The vesical meatus was often rendered patulous and sometimes obliterated; (3) The ejaculatory ducts were also often patulous, allowing regurgitation of the semen into the bladder, and they were also often obstructed. The effects of obstruction on the kidneys and bladder were too well known to require discussion. Dr. Ferguson's method of removal was by the perineal route. He used a prostatic depressor, introduced into the urethra, then elevated in such a manner as to press the prostate down in the perineum. The fingers of the left hand were passed into the rectum as a guide, and then he made one bold incision through the perineum down to the prostatic capsule. Dr. Ferguson exhibited some special instruments devised and used by himself in this operation.

Surgical Treatment of Enlarged Prostate.—Dr. G. E. ARMSTRONG of Montreal exhibited a specially-constructed suprapubic vesical speculum, devised by himself, with a lateral opening which allowed the prostate alone to come well in view in the speculum. The speculum could be packed around with gauze to protect the parts from possible burning, the offending lobe or lobes are then cauterized with the thermocautery. Dr. Armstrong reported seven cases successfully operated on. One point of advantage in this operation lay in the fact that the cauterized surface did not admit of septic absorption. He urged this method in early stages of prostatic hypertrophy.

The paper by Dr. Ferguson and also that of Dr. Armstrong was discussed by Dr. James Bell of Montreal, Sir William Hingston of Montreal; Mr. Irving Cameron of Toronto, and Dr. Elder of Montreal.

The X-Ray as a Therapeutic Agent.—Dr. E. R. DICKSON of Toronto said that the explanation of the rationale of the *x*-ray was at best as yet but a hypothesis. Fortunately, we had a practical proof of its utility as a therapeutic agent in many conditions. Dr. Dickson had used it successfully in the following cases, nævus, lupus vulgaris, tuberculous joints, scleroderma, subacute articular rheumatism (it relieved pain in many cases), neurasthenia, carcinoma of the stomach (this patient gained weight), and in carcinoma of the rectum, which case is also improving.

Dr. G. P. GIRDWOOD of Montreal read a paper on the diagnostic and therapeutic uses of the *x*-rays, and exhibited a number of photographs.

Dr. A. R. ROBINSON of New York said that the *x*-ray largely did away with the knife, and left little scar. It was probable that all superficial cancers could be removed by the *x*-ray if seen early. In a delicate locality, such as the eyelid, the rays should always be used, as paste or the knife would do more harm. When malignant growths had spread deeply, the *x*-ray might be considered our best treatment.

Thursday, September 18.—Third Day.

The first paper was "Remarks on the Sympathetic Ophthalmia," by Dr. G. HERBERT BURNHAM of Toronto, followed by a paper on the "Ocular Manifestations on Systemic Gonorrhœa," by Dr. W. GORDON M BYERS of Montreal.

Excision of the Cæcum.—Dr. O. M. JONES of Victoria, B. C., cited four cases operated on. The first patient lived about two years after. A post mortem proved that the cancerous growth had not recurred at the point of the original operation. Symptoms in all cases were griping pains in the abdomen, loss of weight, and irregular action of the bowels, together with the presence of a mass in the region of the cæcum.

Three Cases of Perforating Typhoid Ulcer Successfully Operated on.—Dr. F. J. SHEPHERD of Montreal reported these cases. Dr. Shepherd had always made use of the lateral incision, and had usually found the perforation near the ileocæcal valve. By this incision the site of the perforation was more easily found than by the medium. He had always closed the incision by turning in the bowel and making use of a continuous Lembert suture, employing fine silk. Other ulcerations in the neighborhood were treated in the same way. Rubber drainage was employed. There was always suppuration in these cases, and usually a hernia resulted. General anæsthesia was always used in these cases. The first case was in a woman of thirty years, with the ambulatory form of her disease. The second was in a woman of twenty-eight years, admitted on about the eighth day. It was of interest in this case that, although perforation had taken place, there was no leucocytosis. The third was in a man, thirty years old, in the third week of the disease. He had been seized with severe pain, and one hour after there was obliteration of liver dulness and marked leucocytosis. All the patients were quite well at the time of the report, with the exception of hernias.

A Case of Total Extirpation of the Urinary Bladder for Cancer.—Dr LAPTHORN SMITH of Montreal reported this case. There had been previous removal of fibroid by myomectomy. This was followed by cystitis, which was treated first by medicine, then by injection, and afterward by drainage by permanent catheter, and then by button-hole operation; when the cancer was detected by the finger. He performed extraperitoneal removal of bladder and affected part of ureter and pelvic glands. Recovery followed the operation, but death occurred on the seventh day from exhaustion.

SECOND INTERNATIONAL CONFERENCE ON THE PROPHYLAXIS OF VENEREAL DISEASES AND SYPHILIS.

Held at Brussels, September 1-6 1902.

(Special Report to the MEDICAL RECORD.)

The International Conference for the Sanitary and Moral Prophylaxis of Venereal Diseases and Syphilis began its discussions on the morning of Monday, September 1, in the General Assembly Hall of the Palais des Académies, at Brussels.

Baron VANDERBRUGGEN, the Belgian Minister of Agriculture, opened the session. In a very documentary discourse he described the practical measures that had been adopted by the various countries, in accordance with the resolutions of the first Conference. He reported the assistance which had been given by the governments to the International Society of sanitary and moral prophylaxis. Belgium had shown its favor to this work. He stated that the objections that had been sent to the Conference were: A harm to science; a stirring up of ideas; a shaking off of indifference and prejudices, and daring to publicly present certain problems—this would be to serve humanity. The art of governing humanity consisted partly in that which was practical, and partly in that which was not; and, in social politics, especially, progress could be realized only in full maturity, at the risk of retrogression. He next described the insufficiency of university teaching, the defects of actual regulation, the necessity of making a clear line of demarcation between sanitary surveillance and the ordinary police laws.

He then welcomed the delegates and the foreign members, and he was warmly applauded in his cordial praise of the fine work of the members of the permanent committee, M. Lejeune, the Minister of State; M. Beco, Director in the Department of Agriculture, and Dr. Dubois-Havenith.

This committee was nominated by acclamation: *President,* M. Lejeune; *Vice-President,* M. Beco; *Secretary,* M. Dubois-Havenith.

Public Prophylaxis of Venereal Diseases in Their Relation to Prostitution.—Dr. H. MINOD, secretary of the International Abolitionist Federation (Geneva), opened the discussion. In regard to the protection of young girls, he held that: (1) The law should have full control over them up to the time of their civil majority; (2) The State ought to encourage the institutions for the protection of apprentices, etc., schools for domestic science, the aid societies, the co-operative associations of production, the restaurants and lodgings for working women, and all measures for the protection of children who have been morally abandoned, etc.; (3) The State ought to ally itself with the aid societies, in order to deliver over to the latter minors who were arraigned on the charge of prostitution, or who had been pointed out as having delivered themselves up to prostitution.

Regarding the duties of the State, he held that: (1) Regulations ought to be abolished; (2) The Code ought to offer the same guarantees to every individual, whatever might be the sex, against seduction, fraud, violence or public scandal, protecting more especially the weak and minors; (3) It was necessary to spread abroad the idea that prostitution was always dangerous; (4) All of the obstacles which were connected with the treatment of these patients should be dissipated.

5. It was necessary to proclaim the principle of unity of morals.

Professor Neisser, Director of the Dermatological Clinic of Breslau, read the next paper on this subject. In the struggle which the State had begun against venereal diseases it ought not to be satisfied with passing resolutions in regard to prostitution; it ought also to take advantage of the numerous occasions which gave it the opportunity of combating the spread of venereal diseases. The most important and the most efficacious means to employ in the struggle against the diffusion of venereal diseases consisted in the spreading abroad as widely as possible the ideas relative to the dangers and to the importance of these diseases. It was necessary not only to teach young men that chastity and continence were not harmful, but also that these virtues were valuable from the medical point of view. All of the measures taken by the authorities with a view of realizing the prophylaxis of venereal diseases, and of combating the fatal consequences of prostitution, ought to be regulated by law. The application of the law ought to be left to the communities and to the self-governing administrations of each district.

It was necessary that the law guarantee to each patient of this kind gratuitous treatment at the hospital, and that it forbid absolutely the remuneration of the expenses incident to this treatment; there should in no case be any demand made on the parents, tutors, or fellow citizens for the reimbursement of hospital expenses. The State should defray all of the expenses of this gratuitous treatment, except in the cases in which the rescue funds and those of the public associations were held responsible for the expenses of the patient.

In all the towns, in all of the important communities, and in all the districts, it was necessary—eventually with the aid of the State—to erect hospitals, to offer hospital services or public consultations, or to appoint physicians with a view of giving gratuitous treatment to these patients, and to distribute medicine without cost to these patients. It was necessary to see that all rules unfavorable to venereal patients should be made to disappear from the hospitals and their consultations. It was preferable to place these patients in the departments of dermatosyphilography, rather than in special hospitals. It was necessary to see that in the public establishments the medical secret and the shame of the patient be respected.

Special measures to be taken were: The creation of a sanitary committee; it should be the central administrative point where all measures should be taken which were necessary to assure the surveillance of venereal patients, and the prophylaxis of venereal diseases. It was necessary to enforce obligatory medical notification under a double form, either with or without mention of the name, as circumstances might indicate. It was necessary to promulgate a law forbidding every person not possessing a medical diploma to treat venereal diseases; the threatened punishments ought to be severe.

The persons who, knowing that they were affected with a venereal disease, continued to have sexual relations, committed a crime, even in the cases in which contamination had not been produced.

Dr. Pierson of Holland pointed out a contradiction in the proportions of the defenders of regulation: "You teach," said he, "that debauchery is fatal; you recommend chastity, and you hasten to tell of the fatal consequences of the non-observance of this advice. What influence can this advice have if you already anticipate the measures which should be taken in the cases in which it is not followed?"

M. Boeck of Norway defended the system used in Norway, of the obligatory declaration by the physicians of the cases of contagious diseases which they had under treatment.

Mme. Sheldon Amos insisted upon the necessity of putting an end to the propagation of immorality among minors. The activity of the school called "abolitionist" had done much for morality. The English government, during the war in South Africa, had affirmed repeatedly that women had never been violated in the course of the war. Was not this fact, new in the world's history, on the part of 250,000 soldiers, a proof of improved morality?

Signor Santoliquido, the eminent director of the Department of Hygiene in Italy, described the progress made in Italy by the system of liberty. Prophylaxis by the hospitals, the dispensaries, the consultations, private intervention accomplishing the work of protection, such was the system which had given such good results in Italy.

Dr. Ferd. C. Valentine of New York proposed the segregation of young girls in special quarters.

M. Petrini of Roumania thought that attention should be paid to those who seduced young girls, and to those who led young boys astray.

Mrs. Drysdale of England praised the favorable results of the régime of liberty.

M. Démétriade of Roumania begged the conference to take account in its resolutions of the particular situation of the small countries.

Dr. Yves Guyot of France remarked that the "abolitionists," although so much derided, had at least one merit. They had made a study of the question. In 1867 no one doubted the excellence of the system employed. To-day the presence of so many members of the conference proved that all the world recognized the necessity of reforms.

Dr. Neisser of Breslau proposed various practical measures. The dissemination of knowledge relative to the verereal diseases, free treatment to each patient, and the prohibition of treatment by charlatans.

M. Verchere of Paris described the results of his experience at St. Lazare. He spoke of the characteristic mental status of fallen girls, and insisted on the necessity of obliging them to care for themselves, whenever they would not voluntarily submit to treatment. He agreed with the opinions of M. Yves Guyot and spoke in terms of praise of his teacher Fournier. The liberty of each one ceased when danger to others commenced.

The Secretary-General announced to the Assembly that a generous donor, Professor Lassar of Berlin, had contributed to the funds of the Society, a sum of a thousand francs. The Conference gave a vote of thanks to Dr. Lassar.

M. Gaston of France insisted upon the necessity of indirect measures, and as the protection of the child-mother and of the illegitimate infant, and prosecution of the wrong doers, etc.

Dr. Merk of Austria discoursed on the excellent methods of the bureaus of hygiene in Austria. He proposed that every physician ought to make a report of every case of contagious disease.

M. Minod of Geneva was opposed to the coercive systems; he approved of submitting minors to guardianship.

Professor Landouzy of Paris wished that contamination might be treated like poisoning, and be made amenable to the common law. He wished to see suppressed as inefficient all regulations.

Sr. Santoliquido, director of the Italian bureau of hygiene, insisted upon the ambiguity of the terms regulationist and abolitionist. He begged the Secretary-General of the Department of Agriculture, M. Beco, to give his opinion on this question.

M. Rethan-Macaré wished that the physician was obliged to denounce the syphilitic patient who was about to marry, thus bringing about a veritable catastrophe

M Beco, Vice-President of the Conference declared that the insufficiency of the systems now in use was proved by the unanimity of the reports, and proposed to separate absolutely the police surveillance from sanitary surveillance

Prof Lesser of Berlin defended absolute medical secrecy, the restricition of which paralyzed medical action

Dr Lane, chief of the service at Lock Hospital, London, defended the hospital system used in England.

Dr Havard, delegate from the United States, described the system employed in America

The Protection of Minors.—Dr. Good of France proposed that the state support an assurance company that would refuse venereal patients. Every candidate for marriage that the society refused would then be suspected of having a venereal disease

M de Mersier explained the measures of legal protection that could be taken

The Organization of Aid and Treatment to be Accorded to Venereal Patients.—Dr. Blaschko of Berlin, explained the necessity of assuring to all venereal patients, without exception, gratuitous treatment

Prof Petrini of Galatz, Roumania, demonstrated the good effects produced by the system that was largely in use in Roumania

Dr Kohn, of Berlin, proposed certain reforms which could be made by means of the aid afforded by the mutual aid societies.

Contagion by Nursing, by Vaccination, Contagion Carried by Clothes, etc.—MM. Havard (United States), Cicero (Mexico), Beco, Professor Landouzy (Paris), Good (France), Castelo (Madrid), Sicard (Paris), Bertarelli (Milan), Drysdale (England), Santoliquido (Rome), de Sturmer (St. Petersburg), Petrini (Bucharest), discussed this question. As regards vaccination the unanimous sentiment was in favor of animal vaccine as the only really safe method

Dr Engel Reimers of Hamburg spoke of measures to be taken in regard to sailors.

Prof Landouzy of Paris insisted on the necessity of introducing both civil and penal responsibility

Dr Pierson pointed out the duty of mothers to nurse their own children.

The conference then discussed various resolutions which had been proposed by Drs. Landouzy, Beco, and Neisser

Proposed Resolutions. By Prof. Landouzy.—Since the régime of regulation, such as had actually been put into practice, had been shown to be inefficient, it was necessary, in the matter of prophylaxis of venereal diseases, to have a common law, equal for men and women.

By M. Beco, Vice-President of the Congress. The conference having determined from the reports which had been submitted to it, and from the unanimous declarations of the speakers who had taken part in the discussions, that the systems of regulation of prostitution actually in use were defective from various points of view, and especially in regard to the point that intervention by the police was harmful to the action of sanitary authority, while its sole object should be that of its disposition. It judged that there was reason in law as in fact to distinguish sanitary action from police action, and to render the first independent of the second, in such a way that prophylaxis of venereal patients, like that of every other transmissible disease, presented a character exclusively hygienic and medical

Amendment by Dr Neisser The State had the right and it was its duty to combat, by means of legal measures, the dangers caused by prostitution from the hygienic point of view. The system actually in use, especially concerned with police authority, ought to be transformed into a sanitary system, which ought to be obligatory only so far as was absolutely necessary for the attainment of an hygienic end

These resolutions had numerous partisans but were not adopted

Civil and Criminal Responsibility of the Contaminator of Either Sex M Bonnevie of Brussels said he had devoted much study to this subject He defended the establishment of both civil and criminal responsibility The laws in effect allowed these two actions to be introduced M Bonnevie cited a case in proof of this If actions of this kind had not been brought more often it was because attention had not been drawn to the matter When it was very difficult to attain prophylaxis in regard to prostitutes possibility of the civil and criminal action would be efficient in protecting innocent individuals, and those worthy of protection.

Individual Prophylaxis.—Although the public authorities had to take measures of prophylaxis against venereal diseases, the duty of taking care of himself was incumbent on each individual for himself. The healthy individual should avoid all dangerous contact with any contaminated person or thing, and the diseased individual should avoid anything which could contaminate others. This being the case, what were the methods of dissemination to which it was necessary to have recourse, to enlighten the youth and the public in general, concerning the individual and social dangers of syphilis and gonorrhœa, as well as concerning the methods of contagion, both direct and indirect, of these two diseases?

Dr Good of France explained various methods of individual prophylaxis, and recalled his brochure, in which he had insisted upon a propaganda of hygiene and morality

Mme. Sheldon Amos of London expressed herself as opposed to the practice of teaching the young that prostitution was inevitable.

Dr. Queyrat of Paris opposed the practice of connecting certain organs and certain functions with the idea of shame.

M. Morsier of Geneva insisted on the necessity of moral prophylaxis.

The next subject was: In what manner can individual prophylaxis be facilitated by means of the aid of institutions, hospitals, dispensaries, refuges, etc , and by medical services which are intended for persons of both sexes afflicted with either syphilis or gonorrhœa?

Dr. Santoliquido, director of the Italian Bureau of Hygiene, described the admirable work accomplished in Italy, definite treatment at home or at the hospital, assured to each one; gratuitous distribution of medicines; reimbursement to the patient for the expenses of the journey, etc. The State directed this immense system.

Prof. Jadassohn of Berne insisted on the necessity of giving to all patients printed instructions explaining the dangers of which they were the source.

Dr. Valentine of New York expressed the wish that medical societies might publish brochures explaining the prophylactic measures which ought to be taken by every one.

Resolutions of the Congress.—At the closing session the conference adopted unanimously the following resolutions:

Resolution of Trois-Fontaines: To give to conscripts arriving from their regiment very condensed, printed instructions on the dangers of gonorrhœa and syphilis To add to this a paragraph pointing out the necessity of always remembering any attack of venereal disease, in order to describe it later to the physician. Also to add perhaps, some brief notes concerning the dangers of alcoholism and the prophylaxis of tuberculosis To be assured that the man leaving the service carried these instructions away with him as he did his military certificate.

Resolution of Neisser, Gaucher-Judassohn It was desirable that a guarantee be made to each patient suffering from venereal diseases of gratuitious treatment, to the largest possible extent It was necessary to see that all factors unfavorable to venereal patients should be abolished from hospitals and consultations. It was necessary to see that in public institutions the treatment respected the medical secret and the shame of the patients.

Resolution of Minod: The most important and the most efficacious means to employ to combat the diffusion of venereal diseases consisted in the dissemination to as great extent as possible of the knowledge relative to the very grave dangers, and to the importance of these diseases. It was necessary especially to teach young men that not only were chastity and continence not harmful, but that these virtues were the most valuable from the medical standpoint.

Resolution of Santiliquido: *Whereas,* The different statistics ought to be in a condition to be compared: 1. It was necessary to establish statistics on a uniform bases. 2. It was necessary to submit the task of their compilation to an international bureau. 3. The President of the International Bureau ought to transmit these propositions that had been submitted to it to the various governments and should take their advice on the formation of this bureau and on the subsidies.

Resolution of Franck: The Conference should issue the resolution that the problem of rational and progressive education of the questions of intersexual order, from the hygienic and moral point of view, should be brought before the institutions for the education of the young in all degrees.

A committee was appointed to determine the preliminaries for the compilation of a treatise, based upon already existing monographs and larger works, which might serve as a tract for the instruction of the general public regarding the dangers of venereal disease, the means of prevention of the same, and the necessity of immediate and persistent treatment. The committee was also instructed to devise means for the popularization of such a work, for its translation into the principal languages, and for its general distribution in all countries of the civilized world.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 20, 1902:

	Cases.	Deaths.
Measles	27	1
Diphtheria and croup	195	28
Scarlet fever	102	7
Smallpox	3	1
Varicella	7	..
Tuberculosis	226	128
Typhoid fever	151	20
Cerebrospinal meningitis	..	..

Persistent Hiccough.—William McDonald reports a case in a young married woman, in which they had to relieve general exhaustion, paresis of abdominal and intestinal muscles, intra abdominal pressure and diminished vascular tone. They gave gelsemium in rather large doses, and its administration was followed by relief, but they do not attribute the cure to the drug, but rather to purging, gavage, rest, tonic, stimulant and electric treatment. In the use of the static machine several larger sparks were directed at the epigastrium, much to the surprise and possibly fright of the patient, and producing immediately a longer interval between the spasms than had been noticed previously. The moral to be found in the history of hiccough is—treat not the name of the disease, not even the disease, but the patient.—*Albany Medical Annals.*

Hepatic Regeneration in Echinococcus Cysts and other Diseases of the Liver.—Rocco Caminiti gives a detailed study of the pathologico-histological condition of the liver in various affections, such as syphilis, malaria, cysts, etc. Regeneration occurs most frequently in the case of echinococcus cysts, but also takes place after other diseases, giving renewed activity of the organ for awhile at least. The conclusion appears to be that these morbid conditions at first affect only a certain number of cells, and progress with more or less rapidity, with more or less lengthened pauses. The regenerative process can intervene and compensate for the damage done, but by reason of the progress of the disease the reparatory process will sooner or later be overcome.—*Il Policlinico.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 20, 1902:

SMALLPOX—UNITED STATES.

THE POST-OPERATIVE HISTORY OF FIFTY CASES OF SIMPLE CHRONIC GLAUCOMA.*

By CHARLES STEDMAN BULL, A.M., M.D.,
NEW YORK.

THE fifty cases of glaucoma, which form the subject of this paper, were all cases of simple, non-inflammatory, chronic glaucoma, occurring in private practice. They all showed increased tension, narrowing of the field of vision, especially on the nasal side, and impairment of central vision. None of the cases, while under observation, ever showed any signs of irritation or inflammation. They were all under my personal observation for a varying length of time, and in all the cases the examinations of the field of vision, visual acuity, condition of tension, and of the fundus, were made by myself. The operative procedure in all cases was iridectomy, and was done on ninety-four eyes. The incision was made sometimes with a very broad lance-knife, and sometimes with a narrow cataract knife, the aim being to make the incision at a distance of two millimeters back of the sclero-corneal margin, so as to include the root of the iris. In other words, a long incision was made and a broad piece of iris was removed. In no case was a second iridectomy done upon either eye of a patient.

Age of the Patients.—The age of the fifty patients varied between twenty-six and eighty-four years. In the decade between twenty and thirty years, there were two cases; in the decade between thirty and forty years, there were four cases; in the decade between forty and fifty years, there were six cases; in the decade between fifty and sixty years, there were five cases; in the decade between sixty and seventy years, there were seventeen cases; in the decade between seventy and eighty years, there were fourteen cases; in the decade between eighty and ninety years, there were two cases.

Sex of the Patients.—Of the fifty patients, twenty-three were men and twenty-seven were women.

Race.—Of the fifty patients, only two were Hebrews, the remainder being native Americans of English, Scotch, French, or Dutch ancestry.

Existing Refractive Condition.—Of the fifty patients, twenty-two were hypermetropic; twelve had simple hypermetropic astigmatism; seven had compound hypermetropic astigmatism; four were myopic; three had simple myopic astigmatism; one had compound myopic astigmatism, and one had mixed astigmatism.

Unilateral or Bilateral.—In forty-four cases the disease involved both eyes, either simultaneously or at a varying interval of time. In six cases but one eye was involved, the other remaining intact as long as the patient was under observation.

Operation.—Iridectomy was done on one eye alone in six cases; on both eyes at a varying interval of time in thirty-one cases; and on both eyes simultaneously in thirteen cases.

Field of Vision before Operation.—The condition of the field of vision before operation was an interesting study, and varied materially in the different patients, and in the two eyes of the same patient. There was concentric narrowing of the field, most marked on the nasal side, in forty-four eyes. There was concentric narrowing of the field with central or paracentral scotomata in fourteen eyes. There was narrowing of the field on the nasal side only in twenty-one eyes. There was loss of the entire nasal half of the field in ten eyes. The field was reduced to a quadrant in three eyes. The field was telescopic in two eyes. The scotomata showed a varying shape, size, and even location at different times, and in some cases entirely disappeared before operation.

In the cases in which the operation was done on both eyes, but with an interval of time between them, the *length of time* which *elapsed* between the two operations was as follows:

In one case, twenty-four hours; in one case, five days; in two cases, one week; in two cases, two weeks; in two cases, three weeks; in four cases, one month; in one case, six weeks; in two cases, two months; in two cases, six months; in seven cases, one year; in three cases, two years; in one case, twenty-six months; in one case, three and a half years; in one case, four years; in one case, six years.

Length of Time under Observation.—The cases were under observation a varying length of time, ranging from one to twenty years, as follows:

Five cases were under observation for one year; ten cases were under observation for two years; eleven cases were under observation for three years; six cases were under observation for four years; five cases were under observation for five years; one case was under observation for six years; one case was under observation for seven years; three cases were under observation for eight years; two cases were under observation for nine years, one case was under observation for ten years; one case was under observation for eleven years; two cases were under observation for twelve years; one case was under observation for eighteen years; one case was under observation for twenty years.

Effect of Iridectomy on Central Vision. Special care was observed in testing the central vision of these cases at various times after the operation, and the results were carefully tabulated; and the following is a brief résumé of these data:

There was a temporary improvement in central vision in seven eyes; there was a permanent improvement in central vision in three eyes; there was immediate failure in central vision in two eyes (these were the eyes with telescopic fields): there was a gradual failure in central vision in fifty-eight eyes; there was maintenance of the vision existing at the time of operation, while under observation, in twenty-four eyes, as follows: In one eye for two years, in seven eyes for three years, in three eyes for four years, in one eye for five years, in one eye for seven years, in seven eyes for eight years, in two eyes for twelve years, and in two eyes for eighteen years.

---

*Read before the American Ophthalmological Society, July 16, 1902.

Condition of the Intraocular Tension after Operation.—There was immediate diminution of tension in eighty-nine eyes; there was permanent diminution of tension in eighteen eyes; there was no effect on tension after operation in five eyes.

Condition of the Color-Fields after Operation.—There was no change in the color-fields in three eyes; there was continuous narrowing of all the color-fields in both eyes of eighteen patients, and in one eye in twenty-six patients; there was loss of the entire color-fields in both eyes of ten patients, and of one eye in nine patients.

Condition of the Field for Form after Operation.—There was loss of the entire nasal half of both fields in four cases; there was loss of the entire nasal half of one field in five cases; there was loss of the entire field in both eyes in one case; there was loss of the entire field in one eye in twelve cases; the field was reduced to a quadrant in both eyes in one case; the field was reduced to a quadrant in one eye in six cases; there was continuous concentric narrowing of both fields in eight cases; there was continuous concentric narrowing of one field in nine cases; the field was unchanged in both eyes in one case; the field was unchanged in one eye in two cases; the field was widened in one eye in one case; in eleven eyes the final result was absolute glaucoma.

Brief Résumé.—In *seven* cases, under observation for a period varying from fifteen months to eleven years, the fields remained as they were at the time of operation. In *six* of these *seven* cases the vision grew slowly worse, and in *one* case the vision was somewhat improved.

In *five* cases the vision remained as it was at the time of operation, or improved while the fields grew narrower.

Age, in itself, did not seem to exercise any definitely bad effect, for some of the most satisfactory results occurred in patients over seventy years of age.

The best results as to ultimate vision occurred in the cases in which the central vision was the best and the fields were the least encroached upon at the time of operation, or, in other words, as soon as the existence of the disease was definitely established.

A careful study of these cases has led me to the conclusion that where the disease undoubtedly exists in both eyes of a patient better results as to visual acuity and the field of vision are obtained by a simultaneous operation on the two eyes. Finally, quoting from a recent statement of my own made before the New York Academy of Medicine: "The operative effect of iridectomy is more certain and undeniable, the earlier it is done. The slightest narrowing of the field, whether for form or color, demands operation, once our diagnosis is made. The curative action of iridectomy stands in direct proportion to the increase of tension. Early iridectomy, while the iris is still mobile, the field but little contracted, and the cupping of the disc slight, very often arrests the disease, at least for a long period, and preserves what sight remains. *Done early*, it offers the best prospects for the arrest of the process, and its effects are either permanent or very prolonged.

Virchow's Ancestry.—A writer in the *Saturday Review* of London says that Virchow, like very many of the greater Germans of the last two hundred years, had in him a large strain of Jewish blood.

MEDICAL RECIPROCITY, OR INTERSTATE EXCHANGE OF LICENSURES.*

By B. D. HARISON, M.D.,
SAULT STE. MARIE, MICH.

MEMBER AND SECRETARY OF MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE; SECRETARY OF THE AMERICAN CONFEDERATION OF RECIPROCATING EXAMINING AND LICENSING MEDICAL BOARDS.

The reciprocal exchange of certificates of registration or licenses by one State with another is not a new or recent idea with the medical profession of the United States. The inconvenience, injustice, unnecessary labor, and expense connected with the change of location from one State to another of a properly-qualified and ethical practitioner has long been recognized and commented upon, and various means have been suggested to overcome this anomaly in American medical practice.

Within the past few years a great many of the States, which either had no medical legislation or a very insufficient medical act, have obtained from their legislatures a more or less effective medical act, and in addition to the prevention of the registration and practice within their borders of incompetents, it has also necessarily, but without purpose, raised a barrier against the holders of reputable and standard qualifications registering and practising in other States, who for one reason or another desire to change their State location, and who before such legislation was effected could comply with the laws relative to medical practice. In other words, while recent legislation in a large number of the States has cut off and given the quietus to a very large and ever-increasing supply of incompetent and fraudulent practitioners, it has also cut off to a large, if, perhaps, to a lesser, extent, the supply of experienced and properly-qualified practitioners from without States.

Therefore, the trend of medical legislation has been more favorable to the recent graduate, while it has not been quite so favorable to the older and more experienced, and yet properly-qualified practitioner. Then, again, as all medical legislation, directly and materially, benefits the people generally, necessary legislative restrictions which prevent a reputable and properly-qualified practitioner from changing his State residence is certainly not productive of benefits that would be otherwise derived from a freer exchange of a good article in the form of a desirable medical practitioner.

A number of the States that recognize the benefits of interstate exchange of licensures have provided more or less fully for such exchange in their respective acts; namely, California, Delaware, District of Columbia, Illinois, Indiana, Kansas, Maine, Michigan, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Porto Rico, Texas, Virginia, Washington, and Wisconsin. Of the above-named States Illinois, New Jersey, Ohio, and one or two others, provide for only partial or modified reciprocity; that is, these States can exchange certificates or licenses obtained by an examination before a State board, provided the holder thereof is possessed of a medical diploma recognized by the two States in reciprocity, and also has a recognized certificate of preliminary education. In other words, the latter States' acts mentioned provide for the going out and coming in of a very recent graduate in medicine, and denies these privileges to the teachers and examiners of such graduate.

As I have before stated, the reciprocal exchange of State medical licenses is not a recent idea. The American Medical Association, at its St. Paul meeting, appointed a committee to report upon the matter. This committee reported favorably at

---

*Read before the Upper Peninsular Medical Society at its annual meeting at Ishpeming, July 15, 16, 1902.

Saratoga last month upon the subject of reciprocity, with certain recommendations looking toward its future promotion, but with no practical result further than directing professional opinion—of course an important factor.

In 1899 the Wayne County Medical Society appointed a commitee to promote medical reciprocity between States, and its secretary, Dr. Emil Amberg of Detroit has done a great amount of work, and has made many valuable suggestions in connection with the subject.

The National Confederation of Medical Examining and Licensing Boards was founded, and its object and existence is expressed in the following constitution:

"*Whereas*, The action in many of the States in requiring a State license before entering on the practice of medicine makes it eminently desirable that the qualification for licensure be fairly equivalent in the various States; and that eventually, by a system of reciprocity, a physician licensed by any one board may obtain the privilege of practising under the jurisdiction of any other board by the proper certification of the license without a new examination, a closer affiliation of the various examining and licensing boards becomes a necessity."

Its membership is made up of individual members of examining and licensing boards of the several States and Territories, and also of physicians not members of examining or licensing boards. It holds an annual meeting, but, beyond discussing the subject of reciprocity in all of its details, so far nothing practical has resulted from its labors.

The Confederation of New England State Medical Boards was founded, and had for one of its objects the reciprocal exchange of State certificates or licenses. Like its sister organization, the National Confederation, it has thus far accomplished but little of a practical nature.

The American Medical Association also has a committee on national legislation, and the subject of reciprocity and uniform medical legislation has received its attention, but without result. This committee is composed of three members, appointed by the president, and an auxiliary committee, composed of one member from each State and Territorial society, represented in the Association, appointed annually by the president, and one member from the Army, Navy, and Marine Hospital Service. I note in connection with such committee that its membership is composed of eminently-qualified physicians, but very few of them have ever had any connection with the work of medical legislation or of medical boards, and, therefore, are not qualified, and could hardly be considered especially competent for such a committee.

It is almost impossible to take up a medical journal published in this country during the past year or so and not find leading articles and communications discussing and approving of the principle involved in medical reciprocity between the several States and Territories.

While an almost unanimous opinion seems to exist relative to the principle involved in reciprocity, there is a great divergence of ideas regarding the practicability of reciprocity and the method by which it can be safely brought about.

Dr. W. L. Rodman of Philadelphia attempted to solve the problem by suggesting the formation of a voluntary national examining board, and this suggestion was supported by the *Journal of the American Medical Association*, and had a great many enthusiastic supporters throughout the country. The committee of the Confederation of State Boards, however, reported against this plan, as follows:

"Against Voluntary National Examining Board.

"On motion of Dr. MacCormack, Dr. A. Walter Suiter, Secretary of the National Confederation of Medical Examining and Licensing Boards, was given the privilege of the floor.

"He said that at a meeting of the confederation, held Monday afternoon, the subject of a Voluntary Board of National Examiners was discussed and subsequently referred to a committee. This committee reported as follows:

"Your committee to whom was referred the proposition originally made and discussed in the medical press by Dr. W. L. Rodman of Philadelphia, for the establishment of a voluntary board of national examiners, with instruction to consider the same, and report thereon to this confederation as to its feasibility, begs leave to report as follows:

"In the opinion of your committee, this confederation cannot endorse nor approve such a proposition for the following reasons, namely:

"1. A voluntary national examining board would have no power, no authority, or legal right to exist.

"2. No guarantee could be given of the continuance or permanency of such voluntary board, even were the laws of the several States so modified as to meet its requirements.

"3. Being a voluntary board, there could be no legal manner of constituting, changing, or limiting its membership, or defining its duties.

"4. Such a board would be representative of the profession only and of the regular profession alone.

"5. Without the endorsement of a State board authorized by law to grant a license to practice, a certificate of qualification from the proposed voluntary board could have no legal value whatever and under the existing laws of the several States, the State examining boards are required to conduct the examinations, and such boards cannot evade, nor surrender, such duty, even if they desired to do so.

"6. To attempt the stupendous task of securing the passage of amendments to the existing laws regulating the practice of medicine in the several States would entail enormous labor and expense, and would probably endanger the laws themselves."

This report was received by the American Medical Association at its Saratoga meeting.

The question then of the method by which the reciprocal exchange of State licenses and the uniformity of standards can be accomplished in the several States is still seemingly as unsettled as it was at the beginning of its agitation. To my mind, however, the question seems a simple one, and the difficulties and hindrances which have heretofore been raised toward its accomplishment, and which have prevented any practical work from being done I believe are more imaginary than real.

Without fear of successful contradiction, I contend that if reciprocity is to become a fact as well as a theory it must be brought about by the influence, action, and coöperation of the several State medical boards, not through individual members of boards or by other members of the profession, who may have the necessary knowledge and enthusiasm, but who actually have no authority or means to do anything practical in the matter.

While the National Confederation of Members of State Examining and Licensing Boards have undoubtedly done good work in the way of education, still it does not represent the authority necessary to accomplish practical things, and its members, who are also members of State boards, could have done more real good by advocating and working for reciprocity within their several State boards than as members of an association which represents no authority. This they have not done to any very appreciable degree.

Dr. Rodman's suggested voluntary national board was the most impracticable scheme yet offered the profession, and should have received no consideration whatever. It has simply clouded the reciprocal atmosphere. As well might be advocated the appointment of a bishop previous to the existence and organization of the parishes, or of the general and colonel before the organization and discipline of the regiments and companies. All the combined efforts at reciprocity so far have been of the "cart-before-the-horse" and of the "tail-wagging-the-dog" variety.

As State boards represent the authority *to do things*, and as its members in nine cases out of ten are responsible for and the authors of the medical acts, or represent those who are so responsible, it seems to me that only through the boards can effective action be had in the matter of reciprocity and uniformity and elevation of the standard of medical requirements for a license to practise medicine in the several States and Territories. This special work should be undertaken by an association or confederation of boards, not by a confederation of board members.

It is, of course, not expected that immediate results will be had in a question of such magnitude as reciprocity and a uniform standard. The idea is to make a correct start, and to grow gradually but surely, and to feel your way as you go. If this is not done, the questions and principles involved will be discredited, and failure will result. It is a question not only of action, but of education and experience as well.

In October, 1901, the Michigan Board passed the following resolution:

"*Resolved*, That the secretary of this board be requested to open communication with the secretaries of the boards of neighboring States, with a view to the adoption, in the near future, of some practical system of reciprocity."

Considering the subject thoroughly before taking any action, and obtaining all the information possible relative to reciprocity, I selected the States of Wisconsin, Indiana, Illinois, and Ohio as objective points to work on, and for the reason that all of the above States had provisions in their medical acts for reciprocity, and were, geographically, in a group known as the Central Western States.

Correspondence elicited the information that all of the above-named States, with the exception of Ohio, were willing to enter into reciprocal relations, of one form or another, with Michigan and with each other. I then suggested a meeting of the executive officers of the several boards interested, which was agreed to, with the result that two meetings were held in Chicago in January and May last, resulting in the formation of the American Confederation of Reciprocating Examining and Licensing Medical Boards.

The following quotations from its constitution are self-explanatory:

"The object of this confederation shall be to establish reciprocal relations between the medical examining and licensing boards of the States, Territories, districts, and provinces of the United States; the purpose of which being that thoroughly worthy and well-qualified physicians and surgeons, who have been legally authorized to practice under the laws of one of said States, Territories, districts, or provinces, may be given authority and be admitted to practice in any State, Territory, district or province represented in this confederation, without a repetition of the tests of qualification to which such practitioner has submitted."

"Any examining or licensing board of any State, Territory, district, or province of the United States, having a medical practice law requiring an examination before said board and requiring thorough professional qualifications as the basis of legal authority to practice in said State, Territory, district, or province, and providing for interstate reciprocity, shall be eligible for membership in this confederation, and may obtain membership by the signature of its authorized representative to this constitution, and maintain such membership by compliance with the requirements of the constitution and by-laws of the confederation.

"It shall be the duty of each examining or licensing board having membership in this confederation to draft and spread on record in its home office a resolution embodying the basis of reciprocal recognition of applicants from other reciprocating States."

The confederation also adopted the two following qualifications as a basis upon which to exchange State licenses with those States in present membership; namely, Indiana, Wisconsin, Illinois, and Michigan:

Qualification No. 1.—That a license or certificate of qualification of at least one year's date, based upon presentation of a satisfactory diploma, and an examination before a State board in specified branches of medicine and surgery, may be accepted at the discretion of a board in lieu of an examination, and as a basis upon which the license of a State may be issued.

Qualification No. 2.—That a license or certificate of qualification, issued by a State board of registration or medical examiners of at least one year's date, based upon presentation of a satisfactory diploma, and upon the recommendation of a State board of registration or medical examiners as to the reputability of the applicant, may be accepted at the discretion of a board in lieu of an examination and as a basis upon which the license of a State may be issued.

It will be noted that simply a policy was adopted relative to reciprocity, leaving it for the individual boards in membership to adopt a standard of preliminary and medical qualifications. This standard must be adjusted by the boards entering into reciprocal relations, but, as far as the standard is concerned, the trend will necessarily be upward.

The dividing line or date between Qualification No. 1 and Qualification No. 2 will have to be set by individual reciprocating boards. No. 1 including only those applicants for the exchange of certificates who have obtained their certificates through a State board examination, and No. 2 including those reputable practitioners who have re-registered under a re-registration clause, or who have obtained their certificates upon the basis of graduation from a recognized or listed college, or who have obtained such licenses previous to the adoption of the dividing line or date between Qualification No. 1 and Qualification No. 2.

Under the law a person who had graduated from a reputable medical college under a two-year course some years ago has the same standing in law that a medical man has who has graduated from the same college under a four-year course at a later date.

Reciprocity would be a failure if it did not take care of those physicians who have been in practice several years, but who graduated from reputable medical colleges previous to the advance of such colleges to a higher standard. If this principle was not acquiesced in, then men of the very highest standing and experience could not be included in any reciprocal exchange of State certificates, and only very recent graduates could obtain the benefits of reciprocity.

If, for example, it is proper for Michigan to receive and register without examination a recent graduate who has passed his examination before the Illinois Board, it also seems proper to recognize the teachers and examiners of such Illinois licentiate without examination. Under the Medical Act of Illinois this cannot be done at present, as it allows only for registration after an examination by a State board. Therefore, Michigan will only be able to reciprocate with Illinois under Qualification No. 1.

Therefore, it behooves the profession of Illinois and of other States having like acts to amend their medical laws, which prevent fully 75 per cent. of their reputable practitioners from receiving their just rights.

Any reciprocal legislation which provides for the present and future practitioner, and ignores the older and experienced practitioner, simply for the reason that the latter has not obtained his certificate of registration through a State board examination, is not only incompetent and unjust, but is also unconstitutional legislation.

One of the great hindrances of reciprocal medical legislation, and of the bringing into effect of the proper exchange of licenses by those States having competent reciprocity clauses in their medical acts, is the almost universal idea held by the profession at large that reciprocity under Qualification No. 2 necessarily means the letting down of the legislative bars, and the unrestricted migration from one State to another of the undesirable and incompetent practitioner, who has obtained registration in the different States through a re-registration clause of the medical acts.

This is not the case, however, for it will be seen that under Qualification No. 2 only graduates of reputable colleges are included, and it leaves it entirely at the discretion of a board as to whether it shall accept an application or not, even though the applicant may be a graduate of a reputable college.

It has been held by some in the past that it would be unconstitutional in law for a State to accord privileges to one registered physician in a State, and deny them to another registered physician in the same State, but there are numbers of decisions of the Supreme Courts in almost every State upholding the principle that when a qualification is exacted the element of prohibition is eliminated if it is possible to obtain the qualification demanded, and such legislation cannot be held as prohibitive legislation.

Therefore, a State has a right to accept with a qualification a physician registered in a State and to reject another registered physician without a similar qualification, although in possession of a similar State license in the same State. This legal question has been a more or less important factor in the past against reciprocity.

Under Qualification No. 1 the raising of the standard of medical education and its uniformity is assured. The boards entering into reciprocity will not, as has been done by the American College Association, set a course in years, as a "four-year course of six months in each year," which may mean little or no actual work accomplished; but will set the course in hours, itemizing each subject and laboratory course. In other words, in the recognition of standards the *fact* will be required as well as the *form*, and every applicant, for the exchange of certificate under this qualification, must sign, and attest to same under oath on an application blank, in which every item of study, including the laboratory work and demonstrations, is itemized, and which represents the standard adopted by the boards in reciprocity.

As this method will promote and assure uniformity and a higher standard in the exchange of certificates under Qualification No. 1 applicable to graduates of medical colleges subsequent to July 1, 1902, it will also promote uniformity and a higher standard in medical colleges, from the fact that graduates, who do not in their course at college take the standard of preliminary and medical education set by the boards holding membership in the American confederation, can obtain none of the benefits of reciprocity. A medical college in the future must do business to be successful upon the quality of its diploma, and its value as a qualification for State license.

For example, a graduate of a Michigan College could possibly go before the Wisconsin Board for examination, and if successful receive the Wisconsin license, but if he did not in his course at the Michigan college obtain a certain standard, he could not, in consequence of having the Wisconsin license obtained by examination, exchange it with a State in reciprocity with Wisconsin unless the Michigan college came up to a certain standard as agreed upon by the two States in reciprocity.

It seems to me necessary, if only from a business point of view, for a college to adopt in its curriculum the requirements of those States having the highest standard, otherwise its students or graduates would be at a disadvantage after graduation, and would not be able to take advantage of the reciprocity regulations in some of the better States.

Those States and colleges adopting the most stringent standard will be able to give more to their licentiates and graduates, and it certainly would be an object for both States and colleges to furnish their licentiates and graduates with the highest quality of a license or diploma.

Every college and State board in the United States will be furnished with the minimum standard of medical and preliminary education adopted by reciprocating boards, and, as I stated previously, it is simply a business proposition for a college to meet the requirements of this standard.

A fact that must not be lost sight of is the overwhelming evidence that the great mass of the profession is determined to elevate the standard, and unless the plan of reciprocity conforms with this idea of a higher standard reciprocity can never be and should not be accomplished.

Three or four State boards uniting means the raising of the standard of every college affected by this union, and if this union means, as it should, only the complete recognition of colleges of the highest standard, then cheap and inferior schools must go by the board. Union with other boards makes it possible for a State board to throw out its inferior schools, for they would not be recognized by the other States in union, and it would then be comparatively easy for a State board in a State in which they are located not to recognize them in consequence.

Another fact that must be remembered is that reciprocal exchange of certificates between States should only be made upon equal terms, and that no State should give or take a certificate except upon the basis of an equal qualification. Therefore, for a time at any rate, complete reciprocity between States will not be possible, but a modified reciprocity will surely, in due course of time, bring about complete reciprocity.

Michigan will have established within a very short time reciprocal relations under Qualifications Nos. 1 and 2, above quoted, with Indiana and Wisconsin, and will undoubtedly reciprocate with

Illinois and several other States under Qualification No 1.

Of course the beginning is not large. In place of starting the culture with a score or more of germs, some healthy, others unhealthy, and still others of an uncertain class or mixed culture, it was thought best to begin the culture of reciprocity by implanting three or four germs of a certain class, knowing that under proper attention and circumstances, the smaller and healthy, but pure culture, would certainly develop in time, and avoiding the risk usually incident to the growth of a larger and mixed culture.

Already I am in receipt daily of inquiries from other States asking for information relative to the American Confederation and its work, and I can safely and surely predict the rapid growth of medical reciprocity and uniformity of qualifications under the auspices of the American Confederation of Reciprocating Examining and Licensing Medical Boards.

To illustrate the *modus operandi* of the confederation's plans in the reciprocal exchange of licensures and in the promotion of a higher and more uniform standard, I append the Michigan Board's resolutions relative to the same passed at its June meeting, and also the blank forms of application adopted under Qualifications No. 1 and 2 quoted before.

The following is the reciprocity clause in the Michigan Medical Act, Sec. 3, Sub-div. 4, "The applicant shall be registered and given a certificate of registration if he shall present a certified copy of certificate of registration or license which has been issued to said applicant in another State of the Union where the requirements for registration shall be deemed by said board to be equivalent to those of this act; provided such State shall accord a like privilege to holders of certificates from this board. The fee for registration from applicants of this class shall be ten dollars."

RECIPROCITY RESOLUTIONS PASSED AT A MEETING OF THE MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE, HELD IN LANSING, JUNE 11, 1902.

Resolved, That this board approves and endorses the action of its members and representatives, Dr. William Bell, President; Dr J. H Cowell, Chairman of the Registration Committee; and Dr. B. D. Harison, Secretary, at the meeting of the American Confederation of Reciprocating Medical Examining and Licensing Boards, held in Chicago, May 20, 1902, in subscribing to the Constitution of the Confederation in and on behalf of the Michigan Board, and in accordance therewith adopts the following qualifications hereinafter designated Qualification No. 1 and Qualification No. 2, as the basis for the reciprocal exchange of certificates under and in harmony with Section 3, Subdivision 4, Act No. 237, Michigan Laws 1899, to wit:

Qualification No 1.—That a license or certificate of registration of at least one year's date, based upon presentation of a satisfactory medical diploma of graduation, and an examination, before a State medical examining board in Specified Branches of Medicine and Surgery, shall be accepted at the discretion of this board in lieu of an examination under Section 3, Subdivision 3, Act No. 237, Michigan Laws 1899, and as a basis upon which a certificate of registration may be issued by the Secretary, with the endorsement of the President and Chairman of the Registration Committee of this board.

Qualification No. 2.—That a license or certificate of qualification issued by a State Board of Registration or Medical Examiners of at least one year's date, based upon presentation of a satisfactory medical diploma, and upon the recommendation of a State Board of Registration or Medical Examiners as to the reputability of the applicant, shall be accepted at the discretion of this board, in lieu of an examination under Sec. 3, Subdiv. 3, Act 237, Mich. Laws 1890, and as a basis upon which a certificate of registration may be issued by the Secretary, with the endorsement of the President and Chairman of the Registration Committee of this board.

Resolved, That the provisions of qualification No. 1, as above carried, shall apply only to those applicants for a Michigan certificate of registration who have obtained their medical diplomas of graduation and State licenses subsequent to July 1st, A. D. 1902, and that the provisions of Qualification No. 2, as above carried, shall apply only to those applicants who have obtained their medical diplomas and State licenses previous to July 1st, A. D. 1902.

Resolved, That under Qualification No. 1 a satisfactory medical diploma shall be of the following minimum standard, viz.:

Minimum Standard of Preliminary Education.

Required under Reciprocity Qualification No. 1.

A certificate of graduation from an approved and reputable high school, academy, college, or university, with the following minimum requirements:

Group I.–English Language.—(a) English Grammar; (b) Rhetoric and Composition.

Group II.–History.—(a) History of the United States, as presented in McLaughlin's History of the American Nation, Johnston's History of the United States, or equivalent text. (b) General History, as presented in Myer's General History, or equivalent text. Greek and Roman History or English History will be accepted as a substitute for General History.

Group III.–Mathematics.—(a) Algebra—Fundamental rules, Fractions, Simple Equations, Involution and Evolution, the Calculus of Radicals and Quadratic Equations, as given in Onley's Complete School Algebra, or Beman and Smith's Elements of Algebra, or some equivalent text. (b) Geometry—Plane Geometry as given in Beman and Smith's Plane and Solid Geometry, or equivalent text. (c) Plane Trigonometry, as given in Wentworth's Trigonometry, or equivalent text.

Group IV.–Natural Sciences.—(a) Physics, as presented in Carhart and Chute's Elements of Physics, or an equivalent text. (b) General Biology, or Botany and Zoology, as presented in Sedwick and Wilson's General Biology, or Spaulding's Introduction to Botany and Kingsley's Comparative Zoology. These courses will be accepted only when accompanied by laboratory work. (c) Chemistry, as presented in Freer's Elementary Chemistry, or an equivalent amount of work in Remsen's Introduction to the Study of Chemistry.

Group V.–Modern Languages.—(a) German or French—The applicant must be able to read French or German. This requires, for one not born to one of these languages, two years of school work.

Group VI.–Latin.—(a) Grammar; (b) Prose Composition; (c) Reading—Four books of Cæsar's Gallic War.

Minimum Standard of Medical Education.

Required under Reciprocity Qualification No. 1

Lectures and Teaching.—30 hours in Electro-Therapeutics; 160 hours in Physiology; 100 hours in Pathology; 80 hours in Histology; 200 hours in Practice of Medicine; 100 hours in Obstetrics; 60 hours in Bacteriology; 15 hours in Medical Jurisprudence; 160 hours in Anatomy; 160 hours in Chemistry and Toxicology; 130 hours in Therapeutics; 30 hours in Hygiene; 200 hours in Surgery; 30 hours in Gynecology; 48 hours in Diseases of the Eye and Ear; 100 hours in Pharmacology.

Laboratory Work and Demonstrations.—240 hours in Anatomy; 120 hours in Pathology; 100 hours in Histology; 120 hours in Bacteriology; 36 hours in Obstetrics; 60 hours in Eye and Ear; 180 hours in Physiology; 180 hours in Chemistry and Toxicology; 200 hours in Surgery; 120 hours in Practice; 32 hours in Dermatology; 120 hours in Gynecology.

The medical course to cover a four years' course of not less than six months in each year, no two courses to be taken in one year and the beginning of the fourth or final six months of such course shall be dated from October preceding the year of the final examinations for the degree of M.D.

Resolved: That under Qualification No. 1 adopted as above, the Specified Branches of Medicine and Surgery in a board's examination shall be as follows: Anatomy, Pathology, Chemistry, Physiology, Therapeutics, Toxicology, Histology, Hygiene, Public Health Laws, Practice of Medicine, Surgery, Obstetrics, Gynecology, Diseases of the Eye and Ear, Bacteriology, and Medical Jurisprudence.

Resolved: That the following colleges fulfil the requirements under Qualification No. 2, adopted as above: (a) Those colleges listed as Reputable Medical Colleges in the United States, March 1, 1902, in the Official List of Legally Qualified Physicians, State of Illinois, March, 1902, from page xxv to page xxxl, inclusive. (b) Those colleges listed in the appendix of the 20th Annual Report of the Illinois State Board of Health from page clxxvi to page cxciii, inclusive, as reputable and legally authorized (c) Those extinct colleges in the United States and Canada which are held reputable by this board

Resolved That the following blank form of application for endorsement of State license under Qualification No 1 be adopted See form, viz: Reciprocity Qualification No 1

Resolved, That the following blank form of application for endorsement of State license under Qualification No. 2 be adopted See form, viz.: Reciprocity Qualification No. 2.

FORM NO. 1.
